instance, SUP and the Ta3 retrotransposon appear to depend more heavily on CpXpG methylation, whereas FWA and possibly Tar17 rely more on CpG methylation. Athila sequences require both types of methylation, because Athila-related transcripts are activated in both cmt3 and met1 mutants.

Despite a nearly complete loss of genomic CpXpG methylation, null cmt3 mutants are morphologically normal, even after five generations of inbreeding. In contrast, met1 mutants exhibit severe developmental abnormalities (3, 7). One explanation for this is that CpXpG and CpG methylation may act in a partially redundant fashion to silence most genes. Viability despite severe loss of genomic methylation makes Arabidopsis an ideal model system for elucidating the roles of DNA methylation in epigenetic and developmental processes.

Ordering Genes in a Flagella Pathway by Analysis of Expression Kinetics from Living Bacteria

The recent advances in large-scale monitoring of gene expression raise the challenge of mapping systems on the basis of kinetic expression data in living cells. To address this, we measured promoter activity in the flagellar system of Escherichia coli at high accuracy and temporal resolution by means of reporter plasmids. The genes in the pathway were ordered by analysis algorithms without dependence on mutant strains. The observed temporal program of transcription was much more detailed than was previously thought and was associated with multiple steps of flagella assembly.

Under the proper conditions, the bacterium E. coli synthesizes multiple flagella, which allow it to swim rapidly. Classical genetics showed that the 14 flagella operons are arranged in a regulatory cascade of three classes (1–5) (Fig. 1). The class 1 operon encodes the transcriptional activator of class 2 operons. Class 2 genes include structural components of a rotary motor called the basal body–hook structure, as well as the transcriptional activator for class 3 operons. Class 3 includes flagellar filament structural genes and the chemotaxis signal transduction system that directs the cells’ motion. A checkpoint mechanism ensures that class 3 genes are not transcribed before functional basal body–hook structures are completed (Fig. 1).

Here, we developed a system for real-time monitoring of the transcriptional activation of the flagellar operons by means of a panel of 14 reporter plasmids in which green fluorescent protein (GFP) (6) is under the control of one of the flagellar promoters (7). This allowed us to extend previous timing studies that depended on lacZ fusions to up to four operons (8, 9). Use of GFP eliminates the need for cell lysis required for lacZ and DNA microarray studies (10–13). Therefore, the present system makes it possible to measure accurately continuous time courses from living cells grown in a multiwell

Fig. 1. The genetically defined hierarchy of flagellar operons in Escherichia coli (1, 2). The master regulator FlhDC turns on class 2 genes, one of which, FlIA, turns on class 3 genes. A checkpoint ensures that class 3 genes are not turned on until basal body–hook structures (BBH) are completed. This is implemented by FlgM, which binds and inhibits FlIA. When BBH are completed, they export FlgM out of the cell, leaving FlIA free to activate the class 3 operons (9, 27, 28). Note that FlgM is transcribed from both a class 2 (figAMN) and a class 3 (figMN) promoter.

Fig. 4. Retrotransposon expression in cmt3 mutants. Blots containing 40 μg of total RNA from whole shoots of line clk-st (left) or cmt3-7 (right) were hybridized with either an Athila probe (A) or a Ta3 probe (B) (10). The positions of molecular size markers (in kilobases) are indicated.

Flagellum plus chemotaxis system
plate fluorimeter (14). Average errors between repeat experiments were less than 10%, compared with errors of at least twofold often associated with expression assays requiring cell lysis and manipulation (10–12).

The flagella system is turned on during the exponential phase of growth. Clustering the fluorescence levels of the operons (Fig. 2A) according to similarity in their expression profiles (10–13) showed that they fall into clusters that correspond to the genetically defined classes 1 and 2 (Fig. 2B). Three of the six class 3 operons are close to the compact class 2 cluster, and the other three are in a separate cluster. This separation is based mainly on different coordinated responses of the operon classes. To determine the timing order, we extended the clustering algorithm with a temporal labeling procedure that hierarchically orders the clusters according to the relative timing of their average expression profiles. Log fluorescence of each reporter strain, normalized by its maximum for each experiment, was set to zero mean and variance one, and clustered by means of a standard single-linkage algorithm with a Euclidean metric (Matlab 5.3, Mathworks) (15). In general, clustering algorithms do not specify an ordering of the clusters. In the resulting dendrograms, as the data are split hierarchically into a tree, pairs of subtrees in each splitting are placed in an arbitrary order. To define the temporal order of expression, we first considered each splitting from the top down and computed the average log fluorescence (normalized by the maximal fluorescence) for the two subtrees, \( \log(f_1) \) and \( \log(f_2) \). Next, we computed \( t_i = - \frac{1}{dt} \log(f_i(t))dt \) (generally the earlier a sigmoidal curve rises, the smaller its \( t_i \). Since log fluorescence is used, the initial rise timing is emphasized.) The subtree with the smaller \( t_i \) was then positioned to the left. The present algorithm was able to correctly order simulated gene cascades. The algorithm is available upon request or at www.weizmann.ac.il/mcb/UriAlon.

The algorithm arranged the operons in the order: class 1 followed by class 2 followed by class 3 (8, 9) (Fig. 2B). Within the class 2 cluster, the promoters were turned on sequentially, with significant delays, in the order fliL, fliE, fliF, fliA, fliB, and fliA (Fig. 2). The observed order corresponds to the spatial position of the gene products during flagellar motor assembly, going from the cytoplasmic to the extracellular sides (1, 2) (Fig. 3). The fliL operon genes form the cytoplasmic C ring, and fliE and fliF genes form the MS ring in the inner membrane, thought to be the first assembled structure (1).

The statistical significance \( P \) value for temporal ordering of each splitting was determined by the fraction of times that a larger \( |t_1 - t_2| \) value was found upon clustering and labeling 1000 randomized data sets generated by randomly permuting the gene coordinates at each time point. Similarly, a \( P \) value for clusters was determined by the fraction of times that a larger splitting distance occurred in the randomized data sets. Clusters with significance \( P < 0.001 \) are marked with filled triangles; \( P = 0.01 \) with an open triangle; and \( P > 0.01 \), no triangles. Temporal ordering of all tree splittings is significant \( (P < 0.01) \), except the splittings marked with a star.

genes, *fliA*, is the last class 2 gene to turn on. A separation of class 3 genes into two kinetic groups was seen, with the filament structural operons *flgK*, *flfD*, and *fliC* activated first, and *flgM* and the chemotaxis operons *meche* and *mocha* going on only after a substantial delay (Fig. 2). Thus, the hardware for the flagellar propeller is expressed before the chemotaxis navigation system (Fig. 3). The genes for motor torque generation, *motAB* in the mocha operon, are in the late class 3 group, and indeed, it has been shown that they can be functionally incorporated long after motors are assembled (16, 17).

When flagella were induced in cells with no preexisting flagella, a temporal separation between most class 2 genes and class 3 genes was observed (Fig. 2B, condition A); whereas in cells with preexisting flagella, the delay between class 2 and the early class 3 genes decreased drastically (Fig. 2B, condition B). This probably reflects the checkpoint in flagella biosynthesis (Fig. 1). When preexisting flagella are present, newly synthesized FlgM is exported from the cells even before new basal bodies are completed. This frees FliA to turn on class 3 genes at an earlier time. Such memory effects may be a general kinetic signature of regulatory checkpoints.

A simple hypothesis for the mechanism underlying the temporal order of promoter activation within classes 2 and 3 is that the DNA regulatory sites in the promoter regions of the operons are ranked in affinity. As the concentration of the relevant transcription factor (FlhDC, FliA) gradually increases in time, the probability reflects the checkpoint in flagella biosynthesis (Fig. 1). When preexisting flagella are present, newly synthesized FlgM is exported from the cells even before new basal bodies are completed. This frees FliA to turn on class 3 genes at an earlier time. Such memory effects may be a general kinetic signature of regulatory checkpoints.

The precise order of transcription of the various operons is probably not essential for assembling functional flagella. This is suggested by complementation experiments in which the motility of flagella mutants was rescued by expression of the wild-type gene from a foreign promoter (1). The detailed transcription order could, however, function to make flagella synthesis more efficient, because parts are not transcribed earlier than needed. From the viewpoint of reverse engineering, this may be exploited to decipher detailed assembly steps from transcription data.

The present experimental method can be readily applied to gene systems in a broad range of sequenced prokaryotes, as well as to eukaryotic genes with well-defined regulatory regions. For example, GFP was used to monitor gene expression on a large scale in yeast (1).8. Studies on various systems could establish whether temporal clustering and memory effects can be a general method in mapping assembly cascades and detecting regulatory checkpoints. It would be important to discover whether, in analogy to the systems-identification principals of engineering, there are ways of mapping additional system motifs, such as feedback loops, by using detailed expression measurements.

Fig. 3. Present kinetic classification of the flagellar operons. The three clusters and the operons within each cluster are arranged by their relative timing according to the temporal clustering results. Positions of the corresponding gene products in the flagellum (1) are indicated in green.
Vitamin C–Induced Decomposition of Lipid Hydroperoxides to Endogenous Genotoxins

Seon Hwa Lee, Tomoyuki Oe, Ian A. Blair*

Epidemiological data suggest that dietary antioxidants play a protective role against cancer. This has led to the proposal that dietary supplementation with antioxidants such as vitamin C (vit C) may be useful in disease prevention. However, vit C has proved to be ineffective in cancer chemoprevention studies. In addition, concerns have been raised over potentially deleterious transition metal ion–mediated pro-oxidant effects. We have now determined that vit C induces lipid hydroperoxide decomposition to the DNA-reactive bifunctional electrophiles 4-oxo-2-nonenal, 4,5-epoxy-2(E)-decenal, and 4-hydroxy-2-nonenal. The compound 4,5-Epoxy-2(E)-decenal is a precursor of etheno-2′-deoxyadenosine, a highly mutagenic lesion found in human DNA. Vitamin C–mediated formation of genotoxins from lipid hydroperoxides in the absence of transition metal ions could help explain its lack of efficacy as a cancer chemoprevention agent.

Molecular oxygen undergoes three successive one-electron reductions (1) to reactive oxygen species (ROS) that can damage cellular macromolecules such as DNA and proteins (2). DNA damage results directly from ROS (3) or from ROS–derived lipid hydroperoxides that break down to form endogenous genotoxins (4, 5). Covalent modifications to DNA by ROS (6) and lipid hydroperoxide–derived genotoxins (7, 8) have been unequivocally characterized in mammalian DNA. Lipid hydroperoxides are formed nonenzymatically by the action of ROS on polyunsaturated fatty acids (PUFAs) (4) or enzymatically from lipoxigenases (LOXs) (9) and cyclooxygenases (COXs) (10). Linoleic acid, the major ω-6 PUFA present in plasma lipids, is converted to 13(S)-hydroperoxy-(E,Z)-9,11-octadecadienoic acid (13-HPODE) by human 15-LOX (11). COX-1 and COX-2 produce mainly 9(R)-hydroperoxy-(E,Z)-10,12-octadecadienoic acid (9-HPODE) and 13-HPODE (10). The HPODEs are subsequently reduced to the corresponding 9(R)- and 13(S)-hydroxy-octadecadienoic acids (HODDEs) through the peroxidase activity of the COXs (12, 13).

Lipid hydroperoxides undergo transition metal ion–dependent decomposition to the α,β-unsaturated aldehyde genotoxins 4-oxo-2-nonenal and 4-hydroxy-2-nonenal (14). 4-Oxo-2-nonenal is a particularly potent lipid hydroperoxide–derived genotoxin (13), which reacts with DNA bases to form heptane-etheno-adducts (Fig. 1) (16). Failure to repair these DNA lesions can lead to mutations (4, 5) or apoptosis (17). The use of vitamin C (vit C) for antioxidant therapy has been advocated because of its ability to scavenge ROS, although its potential for prooxidant activity in the presence of transition metal ions has also been recognized (18). Transition metal ion–mediated decomposition of lipid hydroperoxides is thought to be initiated by a one-electron reduction to an alkoxyl radical (14, 19). This raised the possibility that an alkoxyl radical intermediate would also be formed by a one-electron reduction of the lipid hydroperoxide by vit C (Fig. 1). When a one-electron reduction of hydrogen peroxide occurs, the resulting hydroxy radical (1) is scavenged through a termination reaction either with the vit C radical anion (20) or with vit C itself. We reasoned that when an alkoxyl radical is attached to a PUFA, intramolecular radical propagation could proceed more rapidly than intermolecular vit C–mediated termination reactions. Therefore, the same α,β-unsaturated aldehyde genotoxins observed with transition metal ions (14) may also be observed during vit C–induced decomposition of lipid hydroperoxides (Fig. 1). We have developed liquid chromatography (LC)/atmospheric pressure chemical ionization (APCI)/mass spectrometry (MS)/ultraviolet (UV) methodology to identify the α,β-unsaturated aldehyde bifunctional electrophiles 4,5-epoxy-2(E)-decenal (21), 4-oxo-2-nonenal (14), 4-hydroperoxy-2-nonenal (14, 22), and 4-hydroxy-2-nonenal (14) that could potentially be formed during homolysis of lipid hydroperoxide decomposition (Fig. 2) (23–25).

The prototypic ω-6 lipid hydroperoxide 13-HPODE was allowed to decompose in the presence of vit C in Chlex-treated Mops buffer at pH 7.0 and 37°C. Reaction products were then analyzed by LC/APCIMS with concomitant UV monitoring (24). At early time points, 4-hydroperoxy-2-nonenal was the major product. After 30 min, the 4-hydroperoxy-2-nonenal level started to decline slowly with a concomitant increase in trans-4,5-epoxy-2(E)-decanal, 4-oxo-2-nonenal, and 4-hydroxy-2-nonenal. The reaction was complete at 2 hours, with 4-oxo-2-nonenal, 4-hydroperoxy-2-nonenal, and 4-hydroxy-2-nonenal as the major products (Fig. 3A). At higher vit C concentrations, trans-4,5-epoxy-2(E)-decanal, 4-oxo-2-nonenal, and 4-hydroxy-2-nonenal were produced in greater amounts, and cis-4,5-epoxy-2(E)-decanal could be readily detected (Fig. 3B). The level of 4-hydroperoxy-2-nonenal declined much more rapidly, so that after 2 hours it was undetectable. Unequivocal proof of structure for the aldehydes was obtained by normal-phase LC/tandem MS (MS/MS) analysis (23, 24).

In separate experiments, 13-HPODE was
