Abstract

The perpetual arms race between bacteria and phage has resulted in the evolution of efficient resistance systems that protect bacteria from phage infection. Such systems, which include the CRISPR-Cas and restriction-modification systems, have proven to be invaluable in the biotechnology and dairy industries. Here, we report on a six-gene cassette in *Bacillus cereus* which, when integrated into the *Bacillus subtilis* genome, confers resistance to a broad range of phages, including both virulent and temperate ones. This cassette includes a putative Lon-like protease, an alkaline phosphatase domain protein, a putative RNA-binding protein, a DNA methylase, an ATPase-domain protein, and a protein of unknown function. We denote this novel defense system BREX (Bacteriophage Exclusion) and show that it allows phage adsorption but blocks phage DNA replication. Furthermore, our results suggest that methylation on non-palindromic TAGGAG motifs in the bacterial genome guides self/non-self discrimination and is essential for the defensive function of the BREX system. However, unlike restriction-modification systems, phage DNA does not appear to be cleaved or degraded by BREX, suggesting a novel mechanism of defense. Pan genomic analysis revealed that BREX and BREX-like systems, including the distantly related Pgl system described in *Streptomyces coelicolor*, are widely distributed in ~10% of all sequenced microbial genomes and can be divided into six coherent subtypes in which the gene composition and order is conserved. Finally, we detected a phage family that evades the BREX defense, implying that anti-BREX mechanisms may have evolved in some phages as part of their arms race with bacteria.

Keywords CRISPR; PGL; pglZ; phage defense

Introduction

The ongoing arms race between bacteria and bacteriophages (phages) has led to the rapid evolution of extensive mechanisms to combat phage infection (Labrie *et al*, 2010; Stern & Sorek, 2011). Among these are restriction-modification systems (Tock & Dryden, 2005), abortive infection (Abi) mechanisms (Chopin *et al*, 2005), and the CRISPR-Cas adaptive defense system (Sorek *et al*, 2008; van der Oost *et al*, 2009; Deveau *et al*, 2010; Horvath & Barrangou, 2010). The relatively recent discovery of the complex and abundant CRISPR-Cas system highlights the fact that our knowledge of the arsenal of phage-defense mechanisms encoded in bacterial and archaeal genomes is incomplete. Indeed, accumulating evidence suggest that many additional phage resistance systems present in microbial genomes have yet to be discovered (Stern & Sorek, 2011; Makarova *et al*, 2013; Swarts *et al*, 2014).

A recent study has reported that genes involved in phage resistance, such as restriction-modification enzymes and toxin-antitoxin systems, are non-randomly clustered to specific genomic locations in bacterial and archaeal genomes, forming genomic 'defense islands' (Makarova *et al*, 2011). One of the genes found enriched within defense islands is *pglZ*, a putative member of the alkaline phosphatase superfamily. This gene was previously reported as essential for a unique phage resistance phenotype in *Streptomyces coelicolor* A3(2), denoted phage growth limitation (Pgl) (Chinenova *et al*, 1982). *Streptomyces coelicolor* strains carrying the Pgl system are sensitive to the first cycle of infection by phage Φ C31, but are resistant to phages emerging from this first cycle. Further studies mapped the Pgl phenotype to a cluster of four genes that were able to reconstitute the phenotype upon transfer to a new host (Sumbly & Smith, 2002). These genes include *pglZ*, a putative phosphatase; *pglW*, a serine/threonine kinase domain-containing protein; *pglX*, a protein containing an adenine-specific DNA methyltransferase motif; and *pglY*, a protein containing a P-loop domain (Sumbly & Smith, 2002). The Pgl system was active against Φ C31 and its homologue relatives, but not to any of the other phage that were tested (Laity *et al*, 1993). A molecular mechanism to explain the activity of the Pgl system was never deciphered.

†These authors contributed equally

Based on the enrichment of *pglZ*-domain genes in genomic defense islands, it was suggested that genes containing this domain are involved in phage defense in multiple species (Makarova *et al*, 2011). In this work, we analyzed ~1,500 bacterial and archaeal genomes and found that *pglZ*-domain genes are present in about 10% of these genomes. Moreover, in more than half of the cases, the *pglZ*-domain gene was found embedded in a gene cluster composed of six genes, two of which (*pglZ* and *pglX*) display considerable sequence homology to genes in the Pgl system, and four additional genes that encode a putative protease, a protein with an ATPase domain, a predicted RNA-binding protein, and a gene of unknown function. We hypothesized that this gene cluster forms a novel phage-defense system, which we denote BREX (Bacteriophage Exclusion). Indeed, we show that transfer of this new system from *Bacillus cereus* into *Bacillus subtilis* provides *B. subtilis* with resistance to a broad range of *Bacillus* phages, both virulent and temperate phage. Our data show that phage adsorption occurs in BREX-containing strains, but that neither phage DNA replication nor lysogeny occurs, and that this system does not act via an abortive infection mechanism. This system does not display the Pgl phenotype and hence probably functions through a novel mode of action, different than that of the Pgl system. We provide further evidence that the system methylates chromosomal DNA at a specific motif and that this methylation is likely to be essential for the system's activity. Pan genomic and phylogenetic analyses further show that BREX undergoes extensive horizontal gene transfer and that *pglZ*-containing gene clusters can be divided into six coherent BREX subtypes in which the gene order and composition are conserved. Each BREX subtype contains 4–8 genes, some of which are core genes while others are subtype-specific. Finally, we found that a minority of phages escaped BREX defense, implying that these phages may have evolved anti-BREX mechanisms.

Results

BREX is abundant in bacteria and archaea

Previous analyses of *pglZ*-domain genes demonstrated that this domain is enriched in defense islands of bacteria and archaea (Makarova *et al*, 2011), and documented a number of genes commonly associated with *pglZ*-domain genes (Makarova *et al*, 2011, 2013). To understand whether there is higher order organization among *pglZ* and its associated genes, we performed homology searches and found 144 occurrences of *pglZ*-domain genes in the 1,447 finished bacterial and archaeal genomes analyzed (Supplementary Table S1, Materials and Methods). Remarkably, in 55% of the cases (79 of 144), the *pglZ* gene was embedded within a 6-gene cluster arranged in a highly conserved order in a diverse array of bacteria and archaea (Fig 1A; Supplementary Table S2). Subsequent searches conducted on 5,493 draft genome sequences deposited in NCBI showed that this 6-gene cluster is present in an additional 290 genomes (Supplementary Table S3).

Two of the six genes found in this conserved cluster share homology with genes from the previously reported Pgl system (Sumbly & Smith, 2002): *pglZ*, coding for a protein with a predicted alkaline phosphatase domain, and *pglX*, coding for a protein with a putative methylase domain. The four additional genes include (i) a

Lon-like protease-domain gene, denoted here *brxL*; (ii) a gene coding for a protein with significant structural homology to the RNA-binding antitermination protein NusB (*brxA*, see Supplementary Fig S1); (iii) a gene of unknown function (*brxB*); and (iv) a large, ~1,200 amino acid protein with an ATP-binding motif (GXXXXGK[T/S]), which we denote *brxC*. Although this does not resemble any classical combination of genes currently known to be involved in phage defense, the preferential localization of this conserved gene cluster in the genomic vicinity of other defense genes suggests that it could form a novel phage-defense system. We denote this putative defense system the BREX (Bacteriophage Exclusion) system.

BREX confers resistance to phage infection in *Bacillus subtilis*

To determine whether the BREX system provides protection against phage infection, the complete BREX system from *Bacillus cereus* H3081.97 (Fig 1B) was cloned into a *Bacillus subtilis* BEST7003 strain lacking an endogenous BREX system. Proper integration of the intact system into the *B. subtilis* genome was verified by complete genome sequencing. We then verified, using RNA-seq, that the genes of the integrated system are transcribed in *Bacillus subtilis* when grown in exponential phase in rich medium. Furthermore, using 5' and 3' RACE, we determined that the system is transcribed as two operons with the first four genes, *brxA-brxB-brxC-pglX*, forming a single transcriptional unit, while the last two genes, *pglZ-brxL*, are co-expressed as a second transcriptional unit (Fig 1C, Materials and Methods). The observation that the genes in the putative BREX system are co-transcribed as two long polycistronic mRNAs further supports that they work together as components of a functional system.

Ten *B. subtilis* phages were selected for phage infection experiments, spanning a wide range of phage phylogeny, including Myoviridae (phages SPO1 and SP82G), lambda-like Siphoviridae phages (Φ 105, *rho10*, *rho14*, and SPO2), and SP β -like Siphoviridae phages (SP β , Φ 3T, SP16, and Zeta). Two of the phages are obligatory lytic (SPO1 and SP82G), while the remaining are temperate (Table 1). The phage sensitivity of *B. subtilis* strains either containing or lacking the BREX system was evaluated using both optical density measurements in a 96-well plate format, and double agar overlay plaque assays.

Upon phage infection, the *B. subtilis* strain containing the BREX system showed resistance to seven of the ten phages tested (Table 1). Growth curves of BREX-containing bacteria infected with these seven phages at a multiplicity of infection (MOI) of 10^{-3} – 10^{-4} were similar to the uninfected bacteria, while declines in optical density measurements were observed for the control strain lacking the BREX system, indicating lysis of the infected cells (Fig 1D–F; Supplementary Fig S2). These results confirm that BREX is a phage-defense system that provides protection against a wide array of phages, including both virulent and temperate ones.

In contrast to the protection from phage infection observed with the first seven phages tested, phage resistance was not observed upon infection with phage Φ 105 and its close relatives, *rho10* and *rho14*. Similar kinetics of cell lysis were observed for strains either containing or lacking the BREX system (Fig 1G; Supplementary Fig S2). Considering that phage Φ 105 is estimated to share high (83–97%) genome homology with *rho10* and *rho14* (Rudinski & Dean,

- C Operon organization of the *B. cereus* BREX system integrated in the *B. subtilis* genome. Expression throughout the operons was validated by RNA-seq. Positions of promoters and terminators were inferred by 5' and 3' RACE, respectively.
- D–G Culture dynamics of phage-infected wild-type (black) versus BREX-containing (red) strains of *B. subtilis* BEST7003. Bacterial strains were exposed to phage at time = 0 h, and optical density measurements were read in a 96-well plate format. Each experiment was performed three times with three technical triplicates for each biological replicate. Error bars represent SEM. Shown are representative results for three of the ten phages tested; data for the remaining seven phages are found in Supplementary Fig S2.

Table 1. BREX protection against the phages used in this study.

Phage	Genus	Family	Life cycle	Infection blocked by BREX?	Efficiency of BREX protection ^a
SPβ	SPβ-like	Siphoviridae	Temperate	Yes	> 10 ⁵
SP16	SPβ-like	Siphoviridae	Temperate	Yes	> 10 ⁵
Zeta	SPβ-like	Siphoviridae	Temperate	Yes	> 10 ⁵
Φ3T	SPβ-like	Siphoviridae	Temperate	Yes	> 10 ⁵
SPO2	Lambda-like	Siphoviridae	Temperate	Yes	> 10 ⁵
Φ105	Lambda-like	Siphoviridae	Temperate	No	1
rho10	Lambda-like	Siphoviridae	Temperate	No	1
rho14	Lambda-like	Siphoviridae	Temperate	No	1
SPO1	SPO1-like	Myoviridae	Obligatory lytic	Yes	8 × 10 ² ± 0.02
SP82G	SPO1-like	Myoviridae	Obligatory lytic	Yes	1.8 × 10 ¹ ± 0.08

^aProtection efficiency was calculated as the ratio between the number of plaques formed on the BREX-lacking strain divided by the number of plaques formed on the BREX-containing strain with the same phage titer, using increasing titers. Standard deviation is calculated from a biological triplicate of the plaque experiment.

1979), the inability of the BREX system to protect against these three phages could indicate that this phage family has evolved strategies to counteract the BREX defense, as has been observed with other bacterial defense systems (Bondy-Denomy *et al.*, 2013). If such strategies exist, their identification could provide insight into the mechanism of action of the BREX system. Alternatively, the resistance of phage Φ105 and its relatives to the BREX system could also stem from intrinsic differences in the infection cycle of these phages making them immune to BREX-mediated defense, or because they do not encode a target for the BREX activity.

To further evaluate the level of protection provided by the BREX system against the phages that were tested, plaque assays were performed using increasing phage concentrations. For five of the phages, no plaques were observed when the BREX-containing strain was challenged even with the highest phage concentrations, indicating that the BREX system provides at least 10⁵-fold protection against cell lysis upon infection (Table 1). Plaque assays also confirmed that phage Φ105 and its relatives evade BREX defense, because similar efficiencies of plating and plaque morphology were observed in both BREX-containing and wild-type control strains (Table 1).

Interestingly, for two of the phages tested, SPO1 and SP82G, plaque assays showed only a 10¹-fold reduction in plaque numbers in BREX-containing strains (Table 1). These results were consistent with the observation that incubation of the BREX-containing strain with these two phages for extended periods of time (> 20 h) often resulted in an eventual culture decline occurring at apparently stochastic points in time (Fig 2A). To gain further insight into the nature of the incomplete BREX defense against these phages, we performed a one-step phage growth curve assay (Carlson, 2005) with SPO1. Briefly, this experiment involves mixing SPO1-infected cells with a SPO1-sensitive *B. subtilis* cells and plating them together using an agar overlay method. Phage bursts from successful infections are visualized as a single plaque on a lawn from the SPO1-sensitive *B. subtilis* strain, enabling an evaluation of the number of phages that have adsorbed and completed a successful infection cycle (Materials and Methods). Enumeration of plaques during the first 45 min of the time course infection indicated that the SPO1 phage was able to complete the lytic cycle only in 9 ± 4% of the initially infected cells (Fig 2B). A delay in the kinetics of the phage cycle was also observed, with phage bursts

observed 75 and 105 min following infection of BREX-lacking and BREX-containing cells, respectively (Fig 2B). Together, these results suggest that the BREX system provides significant, but not complete, protection from infection by phages SPO1 and SP82G.

The mode of action of BREX is different than that of the Pgl system

BREX is an apparently complex system with proteins that are predicted to have multiple biochemical activities (e.g., protease, phosphatase, methylase). Fully deciphering its mechanism of action and understanding the role of each of its six proteins in phage defense is expected to be non-trivial and would probably require multiple genetic, biochemical, and structural studies. Here, we set out to provide initial insights into the function of the BREX system.

Due to the homology of a subset of the genes in the BREX system to genes in the Pgl system, we first examined whether BREX also functions through the Pgl mode of action. The Pgl phenotype observed in *S. coelicolor* A3 predicts that the first infection cycle by the phage would be successful, producing viable phage progeny. We used one-step phage growth curve assays to examine the first infection cycle of phage Φ3T in BREX-containing cells. While wild-type control strains displayed phage burst sizes of 61.5 ± 10.2 particles per infected cell (Fig 2C), there was no production of Φ3T phage during infections of BREX-containing cells under similar conditions. To exclude the possibility that productive phage infection could occur, but at later times, experiments were extended to 120 min (three infection cycles in wild-type strains) in BREX-containing cells. Plaques were not observed, even at later times (Fig 2C). These results demonstrate that unlike the *S. coelicolor* Pgl system, the BREX system halts Φ3T production prior to the first round of infection.

Previous experiments with the *S. coelicolor* Pgl system demonstrated that although the Pgl defense system prevents continued propagation of the temperate phage ΦC31, it does not block lysogeny of the phage (Chinenova *et al.*, 1982). To determine whether BREX also permits lysogeny, we examined phage Φ3T integration into the *B. subtilis* genome during infection using a PCR assay. In wild-type control strains, lysogeny was first detected 10 min following phage infection (Fig 2D). However, no evidence for phage integration into

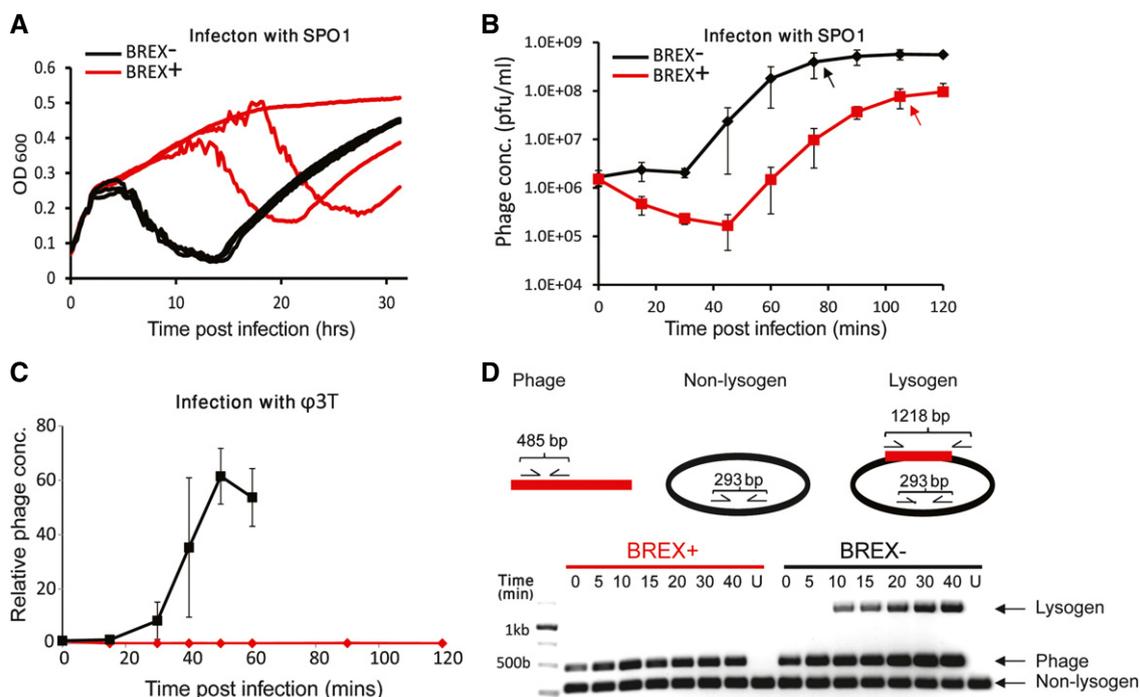

Figure 2. Phage infection dynamics in BREX-containing cells.

Y-axis represents absolute phage concentrations. Black and red arrows point to the time point of maximal burst for BREX-lacking and BREX-containing strains, respectively.
- C** Phage production during a one-step phage growth curve experiment with wild-type (black) and BREX-containing (red) strains of *B. subtilis* BEST7003 infected with ϕ 3T. Error bars represent SD. Y-axis represents relative phage concentrations normalized to the value at the beginning of the infection.
- D** Multiplex PCR assay showing lysogeny during a phage infection time course in the strain lacking BREX (black), but not in BREX-containing strain (red), or uninfected (U) strains. Amplicons for the bacterial DNA, phage DNA, and lysogen-specific DNA are 293, 485, and 1,218 bp, respectively.

the host genome was found in BREX-containing cells. Evaluation of lysogeny in bacterial colonies that survived the phage infection also indicated that none of the surviving BREX-containing colonies were lysogens, while all surviving colonies tested in strains lacking the BREX system were lysogenic for phage ϕ 3T. Together, these results suggest that although BREX and Pgl share a subset of genes, the two systems probably exert their defense through different modes of action.

BREX is not an abortive infection system

One of the common forms of phage defense is abortive infection (Abi), where infected cells commit ‘suicide’ before phage progeny are produced, thus protecting the culture from phage propagation (Chopin *et al*, 2005). Such a phenotype predicts that with a high MOI, where nearly all bacteria are infected in the first cycle, massive cell death will be observed in the culture. To test whether the BREX system works through an Abi mechanism, we infected the BREX-containing *B. subtilis* strain with increasing concentrations of the ϕ 3T phage against which the BREX was shown to provide resistance. Even at an MOI > 1, no significant growth arrest or culture decline was found in the liquid culture, suggesting that the BREX is not an Abi system (Fig 3A).

BREX allows phage adsorption but blocks phage DNA replication

To gain further insight into the stage at which the infection cycle is blocked by BREX, we asked whether phage adsorption is prevented. Adsorption assays showed that ϕ 3T efficiently adsorbs to both BREX-containing and BREX-lacking cells, indicating that BREX does not block adsorption (Fig 3B). We then assayed whether BREX allows phage DNA replication within infected cells. For this, we extracted total cellular DNA (including chromosomal DNA and intracellular phage DNA) at successive time points following a high-MOI infection by ϕ 3T and submitted the extracted DNA to Illumina sequencing. Since host DNA is not degraded following ϕ 3T infection (Supplementary Fig S3), mapping the sequenced reads to the reference *B. subtilis* and ϕ 3T genomes allowed quantification of the number of ϕ 3T genome equivalents per infected cell at each time point. In wild-type control cells, phage DNA replication began between 10 and 15 min following infection, and after 30 min, phage DNA levels were elevated 81-fold relative to that observed at the 10-min time point (Fig 3C). In contrast, no increase in phage DNA levels was observed in BREX-containing cells (Fig 3C). These results indicate that phage DNA replication does not occur in BREX-containing cells and that this system exerts its function at the early stages of the infection cycle.

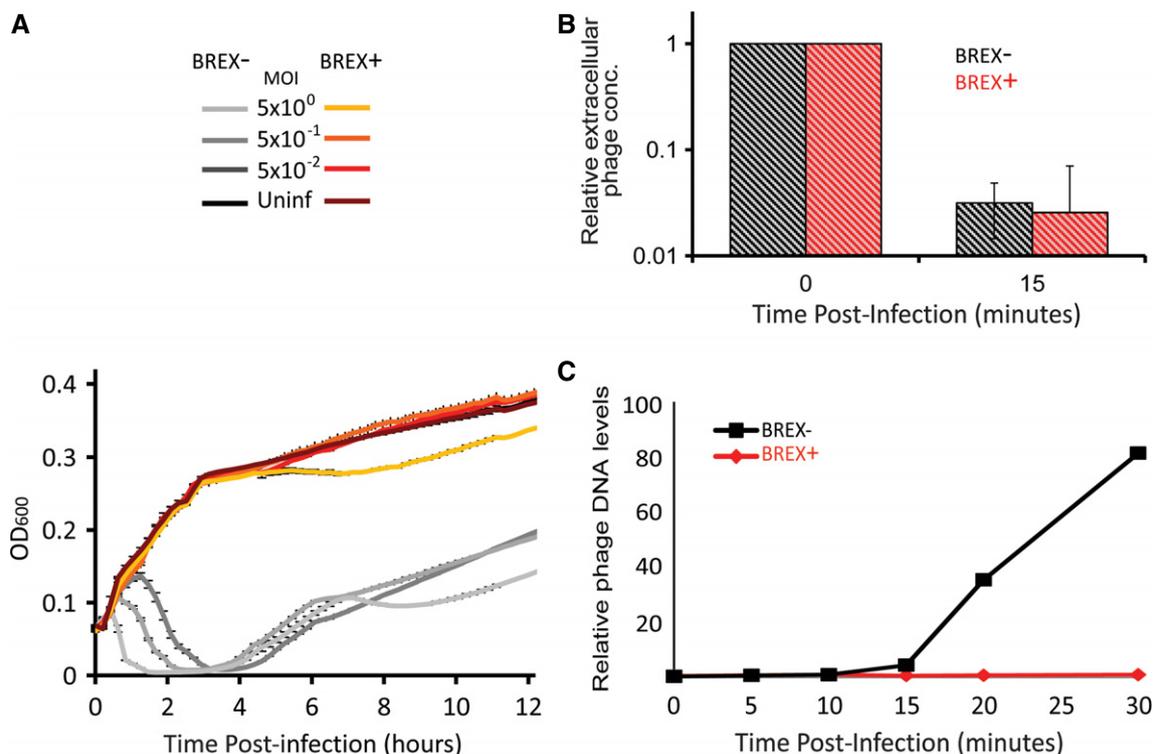

Figure 3. Initial characterization of BREX activity.

- A BREX does not work via an abortive infection mechanism. Increasing the MOI of the $\phi 3T$ infection from 0.05 to 5 shortens the time to culture crash for the BREX-lacking strain, but does not result in culture decline for BREX-containing strain. Error bars represent SD of technical triplicates.
- B The system does not interfere with phage adsorption to bacterial cells. Strains either containing (red) or lacking (black) the BREX system were infected with phage $\phi 3T$ and then chloroform-treated 15 min following infection. The culture was plated on $\phi 3T$ -sensitive *B. subtilis* cells and plaques, representing extracellular, unadsorbed phages, were counted.
- C Phage DNA replication does not occur in BREX-containing cells (red), but is observed in the BREX-lacking strain (black). Y-axis represents relative phage concentrations normalized to the value at the beginning of the infection, as measured by Illumina sequencing.

BREX methylates bacterial DNA but does not degrade phage DNA

The presence of a predicted m6A DNA adenine methylase (the *pglX* gene) in the BREX system prompted us to examine whether either bacterial or phage DNA are methylated in a BREX-dependent manner. To test this, we used the PacBio sequencing platform that directly detects m6A modifications in sequenced DNA (Murray et al, 2012). In DNA extracted from BREX-containing cells, the PacBio platform clearly detected m6A methylation on the 5th position of the non-palindromic hexamer TAGGAG (Fig 4A). While nearly all TAGGAG motifs were methylated in BREX-containing *B. subtilis* cells (Fig 4B), no methylation on this motif was observed in the strain lacking the BREX system. These results suggest that BREX drives motif-specific methylation on the genomic DNA of the bacteria in which it resides.

To examine whether BREX also methylates the invading phage DNA, we extracted total cellular DNA (including chromosomal DNA and intracellular phage DNA) at 10 and 15 min following a high-MOI infection by $\phi 3T$ and subjected the extracted DNA to PacBio sequencing. As in the previous assay, we found that TAGGAG motifs in the bacterial genome were methylated throughout the infection. However, none of the 43 TAGGAG motifs present on the phage genome was found to be methylated at any of the time points sampled during infection.

The presence of bacterial-specific methylation could suggest that the BREX system encodes some kind of restriction-modification activity and that the methylation of TAGGAG motifs in the bacterial genome may serve to differentiate between self and non-self DNA. This hypothesis would predict that deletion of the methylase gene, *pglX*, would be detrimental to the cell, as the genomic TAGGAG motifs will no longer be protected from the putative restriction activity of BREX. However, deletion of the *pglX* from the BREX system that we integrated into *B. subtilis* was not toxic to the cells (Fig 4C). Moreover, BREX-containing strains having a deletion of *pglX* were sensitive to all phage tested (Fig 4D). These results show that *pglX* is essential for BREX-mediated phage resistance and also suggest that the BREX mechanism of action is not consistent with a simple restriction-modification activity.

To further test whether BREX leads to cleavage or degradation of phage DNA, we examined the integrity of phage DNA using Southern blot analyses on total cellular DNA extracted from phage-infected cells at increasing time points following infection. The Southern blot demonstrated extensive replication of phage DNA in BREX-lacking cells and confirmed that no phage DNA replication occurs in BREX-containing cells (Fig 4E). However, in BREX-containing cells, the phage DNA appeared intact, with no signs of phage DNA cleavage or processive degradation (Fig 4E). These

results further imply that BREX inhibits phage propagation in a mechanism other than direct degradation of phage DNA.

BREX can confer mild protection against plasmid transformation

Many defense systems, including restriction enzymes and CRISPR, can confer resistance against both invading phages and plasmids. To examine whether BREX can also block plasmids, we compared plasmid transformation efficiency between BREX-containing and control cells, using three different plasmids (two integrative and one episomal, low copy plasmid, with sizes ranging between 6.7 and 8.8 kb). No considerable reduction in transformation efficiency was observed for the two integrative plasmids, whereas a mild effect (~1 order of magnitude) was observed for the episomal plasmid (Supplementary Fig S4). These results show that plasmids can also be targeted, to a certain extent, by the BREX system. None of the plasmids, however, was blocked as efficiently as many of the phages we tested (> 5 orders of magnitude). This may suggest that the plasmids we used do not contain strong targets for BREX or that BREX specifically targets other characteristics of foreign DNA that are inherent to phage infection.

BREX belongs to a superfamily of defense systems divided into six major subtypes

The experimental results presented above show that BREX is a phage-defense system that contains significant mechanistic complexity. To gain a deeper understanding of the evolution of this system and its relatives, we set out to perform a phylogenetic analysis of its main components.

As indicated above, genes with *pglZ* domains were found in ~10% of all the completely sequenced (finished) genomes analyzed in this study. This domain is present in at least two characterized phage-defense systems: the BREX system described here and the Pgl system described in *S. coelicolor*. To gain a more global view of potential defense systems containing *pglZ*-domain genes, we reconstructed the phylogenetic tree of all the PglZ-domain proteins collected. This tree shows clear clustering of PglZ into several distinct phyletic groups (Fig 5A). The largest group of *pglZ*-domain genes (colored purple in Fig 5A; Fig 5B) corresponds to the BREX system, and PglZ genes belonging to this group were found to be embedded in the typical BREX six-gene cluster we described here. A second, distinct clade of the PglZ tree (red clade in Fig 5A) contains

the *S. coelicolor* *pglZ*, previously shown to be part of the Pgl system. An examination of the genes in the near vicinity of this Pgl clade showed that all *pglZ* genes were embedded in a *pglWXYZ* gene cluster typical of the Pgl system (Sumbly & Smith, 2002), and this clade therefore encompasses the Pgl systems.

In a similar manner, for almost every major clade of the PglZ tree, we were able to detect a coherent set of 4–8 associated genes appearing in a highly conserved order, defining clear organizational multi-gene systems (Fig 5A). The composition and order of these genes was highly coherent within each phyletic group but differed between the clades. We hypothesize that all these systems represent a superfamily of phage-defense systems that includes BREX, Pgl, and four additional related defense systems. Moreover, since the individual clades separate close to the root of the PglZ tree (Fig 5A), and since the six systems we defined are widespread across the entire bacterial and archaeal tree of life (Fig 6), our results suggest that the separation between the systems occurred at an ancient point in the evolutionary history of bacteria and archaea. The BREX system is by far the most common system in this superfamily among the genomes sequenced thus far (Fig 5B). For this reason, we suggest to name the superfamily after this system, with type 1 BREX representing the system described above in this paper, type 2 BREX corresponding to the Pgl system, and types 3–6 representing the

additional putative defense systems belonging to the BREX superfamily.

Overall, 13 gene families were found to be associated with BREX systems (Table 2), largely consistent with previous reports on genes enriched in the vicinity of *pglZ* in defense islands (Makarova et al, 2011). By definition, all systems contain a *pglZ*-domain gene. In addition, all of them harbor a large protein (~1,200 aa) with a P-loop motif. The P-loop motif (GXXXXGK[T/S]) is a conserved ATP/GTP-binding motif that is ubiquitously found in many ATP-utilizing proteins such as kinases, helicases, motor proteins, and proteins with multiple other functions (Thomsen & Berger, 2008). In general, the P-loop-containing genes in the various BREX subtypes share little homology: For example, the *brxC* gene of BREX type 1 and *pglY* gene of Pgl system share homology only across 4% of their protein sequence, and this homology is concentrated around the P-loop motif (Supplementary Fig S5). Despite the low homology, distant homology analysis with HHpred (Soding, 2005) showed that they share a domain of unknown function denoted DUF499 (Table 2). We therefore hypothesize that the P-loop-containing genes in all six BREX subtypes share a similar role in the system and hence refer to these genes (*brxC/pglY*) as having a common function (Table 2 and Fig 5). Apart from the two core genes *pglZ* and *brxC/pglY* that appear in each of the six BREX subtypes, the remaining genes are

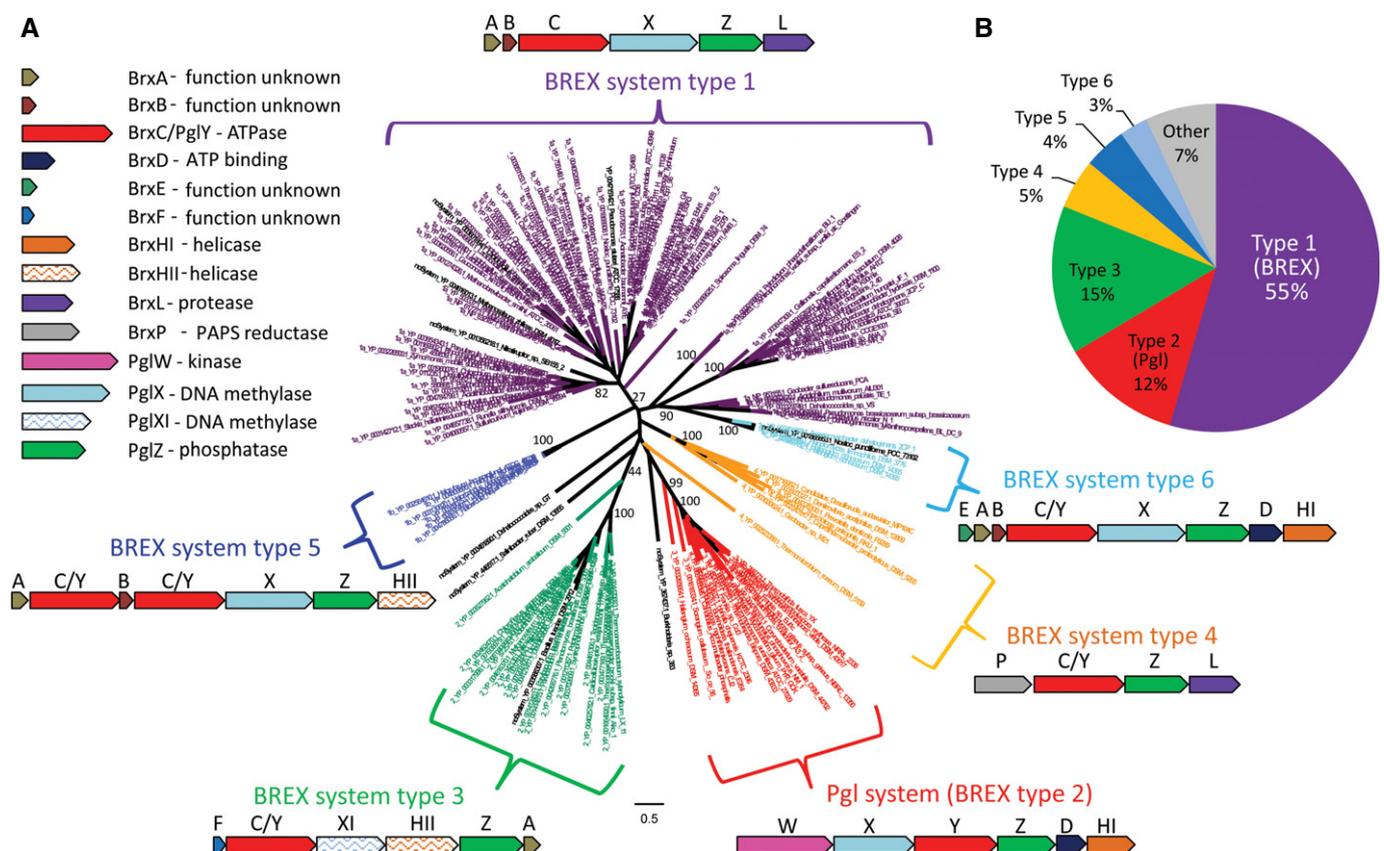

Figure 5. PglZ phylogeny and classification of BREX subtypes.

A Shown is a phylogenetic tree of the PglZ protein instances detected in this study. The tree is color-coded according to the operon organization of the neighboring genes (BREX types). The gene order and genomic organization of each type is illustrated next to its relevant branch on the PglZ tree. Numbers depict bootstrap values.

B Prevalence of the different BREX subtypes within the BREX superfamily of defense systems among the sequenced genomes that were analyzed.

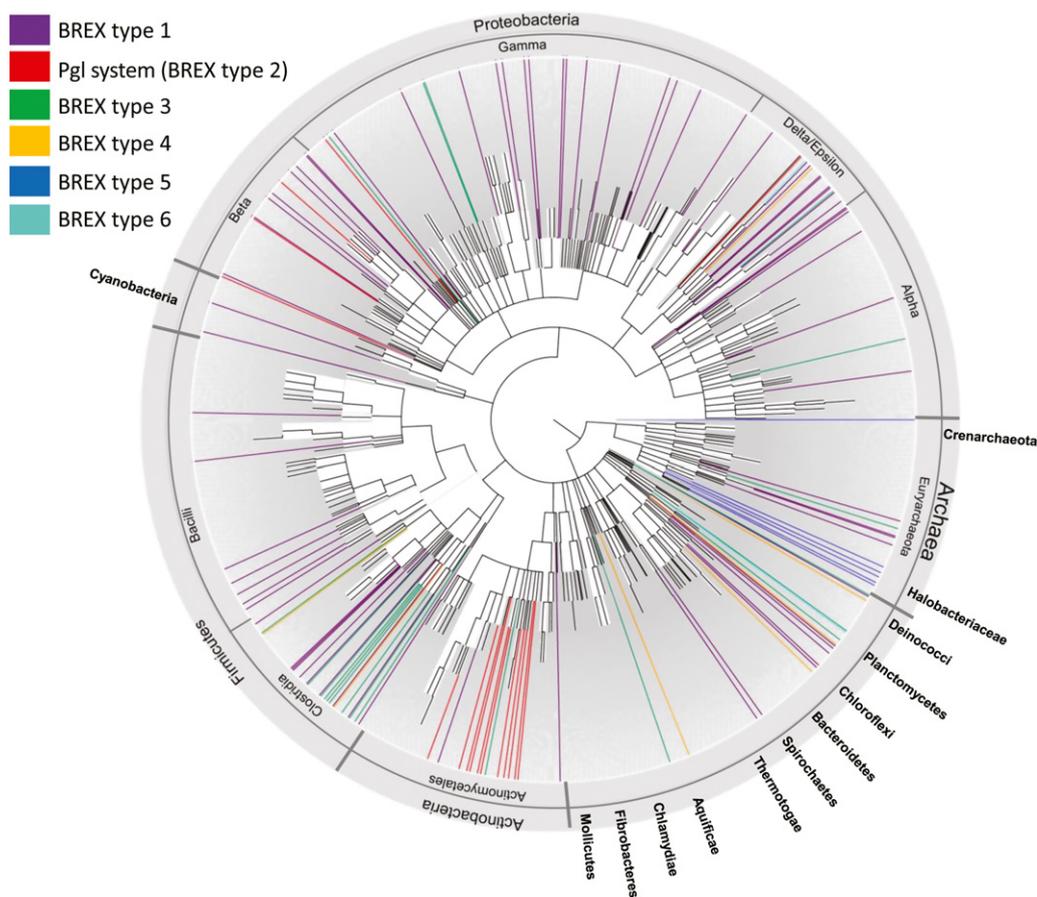

Figure 6. Distribution of BREX systems across the phylogenetic tree of bacteria and archaea.

Shown is the common tree of bacteria and archaea as represented in the NCBI Taxonomy resource (Materials and Methods). Organisms in which a BREX system exists are colored; color code follows the BREX subtype coloring from Fig 5. Extensive horizontal transfer is observed by the lack of coherence between the species tree and the PglZ phylogeny.

subtype specific or are restricted to only a subset of the BREX subtypes.

Although the Pgl system (type 2 BREX) was previously described as being comprised of only four genes (*pglW*, *X*, *Y*, and *Z*) (Sumbly & Smith, 2002), in 89% of the occurrences of this system (16/18 instances), we found that two additional genes, denoted here *brxD* and *brxHI*, were also associated with the system. Given that both these genes appear in the same order in the type 6 BREX system (Fig 5A), one may speculate that these genes play an integral part of the type 2 BREX (Supplementary Table S4). The first gene, *brxD*, encodes a small protein predicted to bind ATP, while the second gene, *brxHI*, encodes a predicted helicase.

The type 3 BREX system was found in 20 genomes and is similar, in terms of gene composition, to the common BREX type 1 (Supplementary Table S5). Both systems contain the short protein BrxA, which shares structural similarity with the RNA-binding protein, NusB (Supplementary Fig S1). In addition, both type 1 and 3 systems contain a gene encoding a predicted adenine-specific DNA methylase (*pglX* and *pglXI* for subtypes 1 and 3, respectively), although the methylase domain differs between the subtypes (pfam13659 and pfam01555 in *pglX* and *pglXI*, respectively) (Fig 5A and Table 2). It is therefore likely that PglX and PglXI perform the same host DNA

methylation function although they do not share sequence homology. BREX type 3 systems do not contain a protein with a Lon-like protease domain, but instead contain a predicted helicase protein, *brxIII* (Fig 5A). In addition, the gene of unknown function *brxB* is replaced with another gene of unknown function, denoted here as *brxF*.

The less abundant type 4 BREX system is composed of four genes, two of which are the core *brxC/pglY* and *pglZ* genes, and the third, *brxL*, contains a Lon-like protease domain (Fig 1; Supplementary Table S6). The fourth gene, which we denote *brxP*, is specific to type 4 BREX and contains a phosphoadenylyl-sulfate reductase domain (COG0175/pfam01507). Interestingly, this domain is associated with the phage resistance DND system that performs sulfur modifications on the DNA backbone, providing an additional link between BREX systems and phage resistance (Wang et al, 2007, 2011; You et al, 2007).

The two least common BREX subtypes, type 5 and type 6, are similar to the type 1 BREX system, but contain some additional variations (Fig 5; Supplementary Tables S7 and S8). In type 5 BREX, the gene containing the Lon-like protease domain is replaced by a helicase-domain gene (which we denote *brxIII*), and there is a duplication of *brxC/pglY*. In subfamily 6, the protease is replaced by *brxD* and *brxHI*, a pair which also appears in type 2 BREX (Fig 5A),

Table 2. Genes composing the BREX systems.

Gene	Subsystems in which gene appears	Associated domains	Domain annotation	Median gene size (aa)
<i>pglZ</i>	Core gene	pfam08665	Alkaline phosphatase	835
<i>brxC/pglY</i>	Core gene	DUF499, DUF2791 (pfam10923)	ATP binding	1,208
<i>brxA</i>	1,3,5,6	DUF1819 (pfam08849)	Unknown function	232
<i>pglX</i>	1,2,5,6	pfam13659 (COG1002/COG0286)	Adenine-specific methylase	1,175
<i>brxL</i>	1,4	COG4930	Lon-like protease	682
<i>brxHI</i>	2,6	COG1201	Lhr-like helicase	712
<i>brxHII</i>	3,5	COG0553	DNA/RNA helicases	965
<i>brxD</i>	2,6	DUF2791 (pfam10923)	ATP binding	442
<i>brxE</i>	6		Unknown function	201
<i>brxB</i>	1,5,6	DUF1788 (pfam08747)	Unknown function	193
<i>pglXI</i>	3	COG0863/COG1743 (pfam01555)	Adenine-specific methylase	920
<i>pglF</i>	3		ATPase	158
<i>pglW</i>	2	COG0515	Serine/threonine protein kinase	1,413
<i>brxP</i>	4	COG0175 (pfam01507), pfam13182	Phosphoadenosine phosphosulfate reductase	774

and an additional gene of unknown function, which we denote *brxE*, is found as the first gene in the cluster.

Overall, 135 of the 144 *pglZ* genes we detected in microbial genomes (94%) were found to be embedded as part of one of the six BREX systems described (Supplementary Table S9), and seven of the remaining *pglZ* genes were clearly part of degraded (probably pseudogenized) systems. In most cases, we found a single BREX system per organism, with only 8 (6.3%) of genomes harboring more than one subtype (Supplementary Table S9). In addition, in 14% (19/135) of the identified systems, one of the genes was missing (Supplementary Tables S2, S4, S5, S6, S7, and S8), possibly representing inactivated systems. Phage-defense systems often encode toxic genes (Makarova *et al*, 2012) or impose a fitness cost (Gomez & Buckling, 2011; Hall *et al*, 2011; Stern & Sorek, 2011), and it is possible that BREX systems also inflict a fitness cost, leading to gene loss in the absence of phage pressure.

Extensive horizontal transfer of BREX systems

An examination of the distribution of BREX systems across microbial species shows that these systems undergo extensive horizontal transfer (Fig 6). First, the distribution of systems across the species tree is patchy; and second, the *PglZ* tree is not consistent with the species tree, with closely related species accommodating distantly related *PglZ* and vice versa. Nevertheless, phylogenetic trees reconstructed from additional BREX genes generally recapitulate the structure of the *PglZ* tree, suggesting that genes within specific BREX systems co-evolve and are co-horizontally transferred (Supplementary Fig S6).

Despite the extensive horizontal transfer observed for the BREX systems, some clades show enrichment in specific subtypes: type 1 BREX is enriched in *Deltaproteobacteria* ($P = 0.001$); type 2 (the *Pgl* system) appears almost solely in *Actinobacteria* ($P = 4.8 \times 10^{-9}$); and type 5 is exclusive to the archaeal class *Halobacteria*. The enrichment of specific subtypes within specific phyla might link the ancestry of these subtypes to the phyla in which they are enriched;

alternatively, phylum-specific BREX subtypes might rely on additional, phylum-specific cellular mechanisms that are not directly encoded in the BREX genes, or provide defense against phages that predominantly attack the specific phyla.

The relative frequency of BREX in archaea (10%) is similar to that observed in bacteria. Only subtypes 1, 3, and 5 are represented in the 111 archaeal genomes analyzed in this study. However, the absence of subtypes 2, 4, and 6 from archaeal genomes could be the result of their rarity and the relative paucity of sequenced archaeal genomes, comprising only 111 out of the 1,447 genomes analyzed.

Frequent interruptions in the adenine-specific methylase *pglX*

One of the strains we obtained when engineering the *B. cereus* type 1 BREX system into *B. subtilis* was not active against any of the tested phages although PCR analysis showed that it contained the complete BREX system. Upon Illumina whole-genome re-sequencing of the engineered strain, we observed a frameshift mutation in the adenine-specific methylase gene *pglX*, resulting from a single nucleotide deletion occurring in a stretch of seven guanine (G) residues at position 2,128 (out of 3,539 bp) of this gene. These results further support the finding that the *pglX* gene is essential for the function of the type 1 BREX system. Moreover, they resemble the results described for the *Pgl* system in *S. coelicolor*, where the sequence of *pglX* was prone to single nucleotide deletions or insertions, leading to phase variation in the activity of the *Pgl* system in a subpopulation of the bacteria (Laity *et al*, 1993; Sumbly & Smith, 2003). We therefore examined more broadly additional evidence for genetic variability of *pglX* in nature.

In 11% of the BREX systems we documented (15/135), the *pglX* gene presented irregularities with respect to the common BREX organization (Fig 7A; Supplementary Tables S2, S4, S5, S6, S7, and S8). These included seven instances of premature stop codons in the middle of the gene, two instances of gene duplication and six occurrences where a full-length *pglX* gene was adjacent to one or more partial forms of *pglX* (with an extreme example in *Methanobrevibacter*

smithii, where five truncated forms of the *pglX* are found near the full-length gene (Fig 7B)). The complete and truncated forms of the methylase usually reside on opposite strands and are accompanied by a gene annotated as a recombinase, possibly involved in switching between the two versions of *pglX*. Indeed, when analyzing the genomes of two strains of *Lactobacillus rhamnosus* GG that were sequenced independently (NCBI accessions FM179322 and AP011548), we found that the *pglX* sequence is identical between the strains except for a cassette of 313 bp that was switched between the full-length and truncated *pglX* genes (Fig 7C). The interchanged cassette was flanked by two inverted repeats suggesting a recombination-based cassette switching possibly mediated by the accompanying recombinase. DNA shuffling via recombination events was previously shown to control phase variation in bacterial defense-related genes to alter the specificity or to mitigate toxic effects of specific genes in the absence of phage pressure (Hallet, 2001; Cerdeno-Tarraga *et al*, 2005; Bikard & Marraffini, 2012). Since no other gene except for *pglX* presented such high rates of irregularities, our results mark PglX as possibly undergoing frequent phase variation, further implicating this gene as the specificity-conferring element in the BREX system or, alternatively, marking it as particularly toxic.

Discussion

In this study, we describe a phage resistance system that is widespread in bacteria and archaea. The most abundant subtype of this system, when transferred from *B. cereus* to the model organism *B. subtilis*, confers complete or partial resistance against phages spanning a wide phylogeny of phage types, including virulent and temperate phages. The abundance of this system and the efficiency with which it protects against phages imply that it plays an important role as a major line of innate defense encoded by bacteria

against phages. Nevertheless, our identification of a family of phages that can completely overcome this system suggests that as in the case of CRISPRs (Bondy-Denomy *et al*, 2013), phages may have evolved molecular mechanisms to shut down or circumvent BREX defense.

The major phage resistance systems that were characterized to date, including the restriction-modification and CRISPR-Cas systems, encode mostly for proteins that interact with and manipulate DNA and RNA molecules. Indeed, the BREX system contains such proteins including methylases and putative helicases. However, BREX systems also contain genes coding for proteins predicted to be involved in the manipulation of other proteins, such as the Lon-like protease, BrxL, and possibly also the predicted alkaline phosphatase, PglZ, and the serine/threonine kinase, PglW. This could imply that the defense mechanism employed by the BREX system takes place later in the infection where phage proteins are already produced and can be manipulated by PglZ and/or BrxL. Alternatively, these BREX proteins might target phage proteins co-injected with the phage DNA early in the infection cycle. Our data suggest that the BREX system acts sometime before phage DNA replication (Fig 3C). Finally, these proteins might also interact with other bacterial-encoded proteins, or with other components of the BREX system itself, to regulate the BREX activity.

Our results show that the *B. cereus* BREX system methylates adenine residues on the 5th position of TAGGAG motifs in the bacterial genome, a function that is probably mediated by PglX. It is therefore likely that this methylation serves as part of the self/non-self recognition machinery of BREX. One may hypothesize that BREX targets non-modified TAGGAG motifs in a way akin to restriction-modification (R-M) systems. However, a few lines of evidence suggest that the BREX is not a simple restriction-modification (R-M) system. First, we failed to detect cleavage or processive degradation of phage DNA in infected BREX-containing

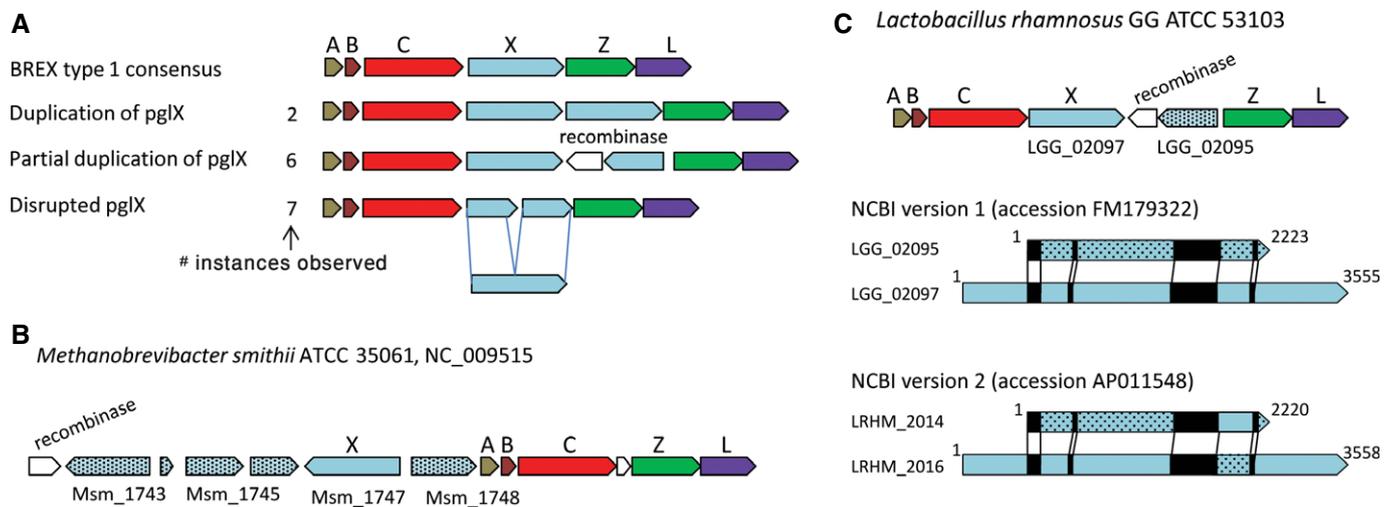

Figure 7. Frequent irregularities in the adenine-specific methylase *pglX* in BREX type 1.

A Irregular genotypes (duplication, inversion, and premature stop codon) associated with *pglX*.

B Genomic organization of BREX system type 1 in *Methanobrevibacter smithii* ATCC 35061.

C Genomic organization of BREX system type 1 in *Lactobacillus rhamnosus* GG. A cassette switch between the short and the long forms of *pglX* is observed when the sequences of two isolates of *Lactobacillus rhamnosus* GG (accessions FM179322 and AP011548, respectively) are compared. Repeat sequences between the short and long forms are shown in black.

cells (Fig 4E). Second, in classical R-M systems, methylation is usually performed on palindromic sites, meaning that both strands of the DNA are modified at the same motif. This allows the R-M methylase to identify hemi-methylated sites during bacterial DNA replication, such that the non-methylated, newly synthesized strand duplexed with a methylated site on the old strand becomes methylated as well. The BREX methylation site, however, is non-palindromic, so that only one strand is being methylated. During DNA replication, therefore, one duplex will carry the methylated site while the other will not; it is not clear how the BREX system would differentiate the non-methylated newly synthesized bacterial DNA from non-methylated DNA of invading phage, and why the bacterial DNA is methylated while the invading phage is targeted. A third inconsistency with the hypothesis that BREX is an R-M system stems from our results with the Δ *pglX* BREX strain. In many R-M systems, deletion of the methylase would be detrimental to cellular growth, because in the absence of DNA modification, the restriction enzyme would cleave the bacterial DNA. However, the Δ *pglX* BREX strain showed no observable growth defect compared to the wild-type BREX strain, but did lose its defensive activity against phage.

The resemblance of the methylated TAGGAG motif to the consensus ribosomal binding site (RBS) of *Bacillus*, AAAGGAGG, may lead to a hypothesis on a putative linkage between the BREX functionality and translation initiation. It remains to be seen, however, whether the same motif is being methylated in all instances of the BREX system or whether each system carries a different motif specificity as in the case of R-M systems.

Some preliminary hints that might help in future elucidation of the BREX mechanism of action can be found in the interchangeability of protein domains between the different BREX subtypes. For example, the DNA methylase common to BREX types 1, 2, 5, and 6 is replaced by BrxP, a protein containing a phosphoadenylyl-sulfate reductase domain. This domain was previously found in the DND phage resistance system where it is involved in performing sulfur modifications on the DNA backbone to differentiate between phage and host DNA (Wang *et al*, 2007, 2011; You *et al*, 2007). It is therefore possible that the PglX methylase and BrxP reductase perform analogous DNA-modifying functions in type 1 and type 4 systems, respectively, which enables BREX to differentiate between phage and host DNA. Similarly, the Lon-like protease in the type 1 and 4 systems is replaced by a helicase in subtypes 2, 5, and 6. It will be of interest to determine the function of the protease and helicase in these systems.

The family of systems we identified here also includes the Pgl anti-phage system of the *S. coelicolor* A3, which is a less common BREX variant denoted here as a type 2 BREX. Four genes, *pglW*, *pglX*, *pglY*, and *pglZ*, were shown to be necessary and sufficient for the Pgl phenotype (Sumbly & Smith, 2002). However, in this study, we identified two additional genes, encoding an ATP/GTP-binding protein (*pglD*) and a helicase (*pglHI*) that are almost always associated with the four Pgl genes in type 3 systems (Fig 5). It is possible that the unique Pgl phenotype observed for *S. coelicolor* A3 and its phage Φ C31 stems from an incomplete BREX system found in that strain, perhaps due to mutational inactivation of *pglD* or *pglHI*. This hypothesis is also in line with the lack of Pgl defense against any other phage except for Φ C31 and its homoimmune relatives. Consistently, the type 1 system we tested in *B. subtilis* seems to confer resistance also against the first cycle of phage infection and hence

could not be defined as reproducing the Pgl phenotype. An alternative explanation might be that the *pglD* and *pglHI* genes are an integral part of the system but do not participate in the act of defense itself, as in the case of the *cas1* and *cas2* genes in the CRISPR-Cas system (Terns & Terns, 2011).

The abundance of *pglZ* in microbial genomes and its preferred localization to defense islands has previously been reported by Makarova *et al* (2011, 2013). They observed that *pglZ* is frequently found associated with additional genes, and suggested its involvement in a complex PGL-like anti-phage system. Our results now divide *pglZ*-containing gene clusters into several coherent types in terms of gene composition, gene order, and genomic organization, suggesting that these subtypes act as discrete functional units. Furthermore, the genes composing the subtypes of these systems are co-evolving and horizontally transferred together, as observed from the similar phylogeny of the two core proteins, PglZ and BrxC/PglY (Fig 5; Supplementary Fig S5).

It is now well appreciated that the arms race between bacteria and phage is playing a major role in shaping the evolution of bacterial and phage genomes (Stern & Sorek, 2011). The discovery of a major additional line of defense in bacteria may, therefore, shed more light on this complex arms race. Previously, deep understanding of the molecular mechanism of complex phage resistance systems such as restriction-modification and CRISPR-Cas has led to revolutions in molecular engineering applications (Cong *et al*, 2013; DiCarlo *et al*, 2013), as such systems provide both specificity and targeting of nucleic acids. With further mechanistic studies into the potentially functional sophistication encoded by the multi-gene BREX system, this system might in the future prove to be yet another powerful molecular tool.

Materials and Methods

Genomic data and molecular phylogeny of the PglZ protein

A set of 1,447 completely sequenced prokaryotic genomes (1,336 bacterial and 111 archaeal genomes, Supplementary Table S1) were downloaded from the NCBI FTP site (<ftp://ftp.ncbi.nih.gov/genomes/Bacteria/>) in September 2011 and used for subsequent analyses. Several PglZ protein sequences were used as a query in a PSI-BLAST search against the 1,447 prokaryotic genomes with an inclusion threshold *e*-value of 0.001. Proteins that did not contain the *pglZ* domain or that were shorter than 600 aa were filtered out. The remaining protein sequences were used to build a PglZ tree as follows. Amino acid sequences were aligned using the MAFFT algorithm (Kato *et al*, 2002). The Fourier transform approximation was disabled, and substitution rates were modeled with JTT (Jones *et al*, 1992) and BLOSUM45 matrix, which is suitable for diverged sequences. The gene tree was reconstructed using the probabilistic RAXML algorithm, with 100 bootstrap replicates, substitutions modeled with JTT (Jones *et al*, 1992), while allowing for rate variability among sites.

Identification of BREX types 1–6

System types were characterized based on manual observation of phyletic clusters in the PglZ tree. The specific genes associated with

each PglZ phyletic type were defined using the IMG genome browser (<https://img.jgi.doe.gov/cgi-bin/w/main.cgi>). A representative protein sequence of each of the individual genes (Table 2) was then used as query in a PSI-BLAST search with an inclusion threshold *e*-value of 0.05. Only gene clusters containing the two core genes and at least two additional genes were considered, under the added constraint that the genomic distance between the first and last genes in the system should be under 30 kb. In the case of PglY, homology was based on the shared motifs (the P-loop motif GXXXXGK(T/S) (DUF2791)) and DUF499 combined with the conserved size of the gene in the different subtypes (~1,200 aa). The filtered clusters were manually assigned to systems according to gene content. Only clusters containing the complete set of genes or missing one non-core gene were included in the final set (Supplementary Tables S2, S3, S4, S5, S6, S7, and S8). In the case of BREX 2, systems missing both pglD and pglHI were also included. The blastx program was used to scan intergenic regions in the clusters for unannotated genes.

Protein domains were annotated using the conserved domain database (CDD) (Marchler-Bauer & Bryant, 2004) and HHpred (Soding, 2005). In the latter case, queries were carried out using representative sequences against the PDB, SCOP, interpro, pfam, smart, tigrfam, and COG databases using default search parameters.

The consensus organisms tree for Fig 6 was derived from the NCBI 'common tree' downloaded from the NCBI Taxonomy portal at <http://www.ncbi.nlm.nih.gov/Taxonomy/CommonTree/wwwmt.cgi>. In order to check whether subtypes are overrepresented in specific bacterial phyla, the two following ratios were compared, using a hypergeometric statistical test: (i) number of instances of a specific subtype in a specific phylum/total number of the specific subtype in bacteria; (ii) total number of genomes of the specific phylum analyzed/total number of bacterial genomes analyzed. *P*-value ≤ 0.05 was considered statistically significant following Benjamini and Hochberg correction for multiple testing.

Strain construction

The type 1 BREX system was amplified in fragments from the *B. cereus* H3081.97 genome (kindly provided by A. Hoffmaster and C. Beesley) from position 89,288–103,514 (GenBank ABDL02000007.1). The PCR-amplified fragments were transformed into *S. cerevisiae* together with the pYES1L vector (Invitrogen), where they were assembled *in vivo* into a circular plasmid. Genomic DNA from the transformed *S. cerevisiae* strain was then transformed into *E. coli* BL21-AI where the plasmid was amplified, and then integrated into the *proB* gene in *B. subtilis* BEST7003, along with a chloramphenicol resistance cassette. PCR and Illumina-based whole-genome sequencing were performed to confirm the presence of the intact BREX system within *B. subtilis* BEST7003. Control strains contain only the chloramphenicol resistance cassette integrated at the *proB* locus. The *pglX* deletion strain was constructed in a manner similar to that described above, but with PCR fragments that created a deletion from position 94,655–98,163 (GenBank ABDL02000007.1), leaving only 31 nucleotides of the *pglX* gene.

Growth dynamics of phage-infected cultures

Overnight cultures were diluted 1:100 in LB media supplemented with 0.1 mM MnCl₂ and 5 mM MgCl₂ and then grown to logarithmic

phase. Standard phage infections were performed at multiplicities of infection ranging from 10⁻³ to 10⁻⁴. High concentration phage infections were performed at multiplicities of infection ranging from 0.05 to 5. Optical density measurements at a wavelength of 600 nm were taken every 13 min using a TECAN Infinite 200 plate reader in a 96-well plate.

Plaque assays

Small drop plaque assays were initially performed using 0.75% agar plates containing bacterial cultures that were diluted 1:13 in LB media supplemented with 0.1 mM MnCl₂ and 5 mM MgCl₂. Serial dilutions of the phage between 2 × 10⁰ and 2 × 10⁵ pfu were spotted on these plates, and plaques were counted after overnight growth at room temperature. Further confirmation of plaque numbers was performed by an agar overlay assay. The bottom agar was composed of LB media supplemented with 0.1 mM MnCl₂ and 5 mM MgCl₂ and 1.5% agar. The top agar was prepared by diluting logarithmic phase bacterial cultures 1:30 in LB media supplemented with 0.1 mM MnCl₂ and 5 mM MgCl₂ and 0.5% agar with the addition of serial dilutions of the phage. Plaques were counted after overnight growth at room temperature.

One-step phage growth curve assays

One-step phage growth curve experiments were performed as described by Carlson (2005). Logarithmic phase cultures were infected with either phage SPO1 or Φ 3T at an MOI of 0.05. The infection culture was diluted 1:10,000 after 18 min of growth at 37°C, to reduce the likelihood of phage infection following cell lysis. To evaluate the number of infective centers and extracellular phage present in the infection mixture, samples were taken throughout the phage infection time course, were mixed with a phage-sensitive *B. subtilis* strain, and were plated using the agar overlay method together, as described above. Phage adsorption was inferred by evaluating the number of extracellular phage present in the mixture at early time points. This was assayed by mixing the infection mixture with chloroform, incubating it at 37°C for 4 min, followed by a 4-min incubation on ice, and 30 min at room temperature. The aqueous phase was then mixed with a phage-sensitive strain and plated using the agar overlay method described above. The derived results allow evaluation of the extracellular phage levels, since the chloroform will kill all bacteria, including those with phage adsorbed, and at early time points, phage have not yet assembled inside the cell and are therefore unable to form plaques. A drop in extracellular phage levels indicates that adsorption has occurred.

Phage infection time courses, genomic DNA sequencing, and methylation analysis

Phage infection time courses for methylome analysis, detection of lysogeny and relative phage abundance were performed at an MOI of 4. Cell pellets were washed three times in 10 mM Tris pH 7.4 to remove unadsorbed phage, followed by DNA extraction. DNA library preparations and sequencing for methylome analysis were performed at the Yale Center for Genome Analysis.

To determine the relative abundance of bacterial and phage Φ 3T DNA levels, DNA was first fragmented using NEBNext dsDNA

Fragmentase (NEB) as per manufacturer's instructions. The relative abundance of bacterial and phage $\Phi 3T$ DNA levels was determined by Illumina sequencing of the DNA libraries of phage $\Phi 3T$ -infected time course cultures. Resulting sequence reads were mapped to the phage and host genomes as previously described (Wurtzel et al, 2010). Reads from DNA sequences shared by both *B. subtilis* BEST7003 and phage $\Phi 3T$ DNA were discarded from the dataset. The remaining mapped reads were enumerated to compare the number of reads mapping to the *B. subtilis* BEST7003 DNA sequence relative to phage $\Phi 3T$ DNA at each time point, normalized to the genome size.

Detection of phage lysogeny

Genomic DNA sequencing of a lysogen containing phage $\Phi 3T$ was performed using Illumina sequencing to determine the DNA sequence of the $\Phi 3T$ phage, and the site of phage integration in the genome. Integration of the $\Phi 3T$ phage was determined to be at a GTAGG site on the *B. subtilis* BEST7003 bacterial genome at position 2,106,060–2,106,064. Multiplex PCR assays were used to detect phage $\Phi 3T$ DNA, *B. subtilis* BEST7003 DNA, and the novel junction created in the lysogenized strain. Primers used to detect phage $\Phi 3T$ were GAGGTTTCGCTAGGGCGAAAT and TCTCTGCTTTGATTCGTC-CATGA. Primers for detection of *B. subtilis* BEST7003 and the unique junction found in the lysogen were TGCCTGCATGAGCT-GATTTG and GGCAGGAATGAATGGTGGATATTG, and TCATGCTCGGATTTGCGAT and TGCCTCCTTTGATTTTGTACC, respectively.

Plasmid transformation assays

Competent cell preparation and transformation for BREX-containing and control *B. subtilis* BEST7003 bacteria were performed as described in Itaya and Tsuge (2011). The integrative plasmids pAX01 (7.8 kb) and pDG1731 (6.7 kb) and the episomal plasmid pHCMC05 (8.8 kb) were obtained from the Bacillus Genetic Stock Center (BGSC). pHCMC05 was further engineered to replace the chloramphenicol resistance gene by a spectinomycin-resistance gene. The spectinomycin-resistance gene was amplified from the pDG1731 plasmid using primers AAAAATTTAGAAGCCAAT-GAAATC and CCCCTATGCAAGGTTTAT and integrated between the MfeI and BsaBI restriction sites of pHCMC05, thus replacing the chloramphenicol resistance gene. 100 fmol of plasmid was used per transformation. Before plating the competent bacteria on selection plates, a live count was performed using a series of serial dilutions plated on LB plates. Transformation efficiency was calculated as the number of colonies that grew on selection plates divided by the live count on LB plates.

Acknowledgements

We thank Udi Qimron, Debbie Lindell, Ilana Kolodkin-Gal, Uri Gophna, Daniel Dar, Azita Leavitt, Sarit Edelheit, Asaf Levy, and Eran Mick for comments and stimulating discussions. We also thank M. Itaya for kindly providing the BEST7003 strain, the BGSC for phage isolates and plasmids, Yana Gofman for assistance and advice in structural analyses, and A. Hoffmaster and C. Beesley

for kindly sharing the *B. cereus* lysate. R.S. was supported, in part, by ISF (personal grant 1303/12 and I-CORE grant 1796), ERC-StG Program (grant 260432), HFSP (grant RGP0011/2013), the Abisch-Frenkel Foundation, and a DIP grant from the Deutsche Forschungsgemeinschaft. O.C. was the beneficiary of a postdoctoral grant from the AXA Research Fund.

Author contributions

HS conceived the project, identified the systems, and performed most of the computational analyses. TG designed the experiments, performed them, and analyzed the results. EW established the phage infection platform with the *B. subtilis* BEST7003 host. OC performed the phylogenetic analyses. SD analyzed the transcriptome and genome data. YCA performed infection experiments. SA performed some of the computational analyses. GO designed and performed the plasmid transformation efficiency experiments, and assisted with the pglX deletion strain. RS analyzed the results, overviewed the project, and wrote the paper together with TG and HS.

Conflict of interest

The authors declare that they have no conflict of interest.
