Formation and evolution of aerosols and droplets inhomogeneities (clusters) are of fundamental significance in many areas of environmental sciences, physics of the atmosphere and meteorology (e.g., smog and fog formation, rain formation), transport and mixing in industrial turbulent flows (such as spray drying, pulverized-coal-fired furnaces, cyclone dust separation, abrasive water-jet cutting) and in turbulent combustion (see, e.g., Refs. [1–8]). The reason is that the direct, hydrodynamic, diffusional, and thermal interactions of particles in dense clusters strongly affect the character of the involved phenomena. Thus, e.g., enhanced binary collisions between cloud droplets in dense clusters can cause fast broadening of droplet size spectrum and rain formation (see, e.g., Ref. [8]). Another example is combustion of pulverized coal or sprays whereby the reaction rate of a single particle or a droplet differs considerably from the reaction rate of a coal particle or a droplet in a cluster (see, e.g., Refs. [9,10]).

Analysis of experimental data shows that spatial distributions of droplets in clouds are strongly inhomogeneous (see, e.g., Refs. [11–14]). Small-scale inhomogeneities in particle distribution were observed also in laboratory turbulent flows [15–18].

It is well known that the turbulence results in a relaxation of inhomogeneities of concentration due to turbulent diffusion, whereas the opposite process, e.g., a preferential concentration (clustering) of droplets and particles in turbulent fluid flow still remains poorly understood.

In this study we suggest a theory of clustering of particles and droplets in turbulent flows. The clusters of particles are formed due to an instability of their spatial distribution suggested in Ref. [19] and caused by a combined effect of a particle inertia and a finite velocity correlation time. Particles inside turbulent eddies are carried out to the boundary regions between them by inertial forces. This mechanism of the preferential concentration acts in all scales of turbulence, increasing toward small scales. An opposite process, a relaxation of clusters is caused by a scale-dependent turbulent diffusion. The turbulent diffusion decreases towards smaller scales. Therefore, the clustering instability dominates in the
Kolmogorov inner scale $\eta$, which separates inertial and viscous scales. Exponential growth of the number of particles in the clusters is saturated by their collisions.

In our previous study [19] we suggested and qualitatively analyzed an idea that inertia of particles may lead to their clustering. Later this idea was questioned by our quantitative analysis [20, 21] of the Kraichnan model of turbulent advection of particles by the $\delta$-correlated in time random velocity field. It was proved that the clustering of inertial particles does not occur in the Kraichnan model. The latter result may be considered as a counterexample.

The main quantitative result of the theory of clustering instability of inertial particles, suggested in this study, is the existence of this instability under some conditions that we determined. We showed that the inertia of the particles is only one of the necessary conditions for particles clustering in turbulent flow. In the present study we found a second necessary condition for the clustering instability: a finite correlation time of the fluid velocity field which in the suggested theory results in a nonzero divergence of the field of Lagrangian trajectories. This time is equal zero in the above-mentioned Kraichnan model (see Ref. [22]), which was the reason for the disappearance of the instability in this particular model.

In this study we used a model of the turbulent velocity field with a finite correlation time that drastically changes the dynamics of inertial particles. In the framework of the model of the velocity field, we rigorously derived the sufficient conditions for the clustering instability. We demonstrated the existence of the new phenomena of strong and weak clustering of inertial particles in a turbulent flow. These two types of the clustering instabilities have different physical meanings and different physical consequences in various phenomena. We computed also the instability thresholds that are different for the strong and weak clustering instabilities.

**II. Qualitative Analysis of Strong and Weak Clustering**

**A. Basic equations in the continuous media approximation**

In this study we used the equation for the number density $n(t, r)$ of particles advected by a turbulent velocity field $u(t, r)$:

$$\frac{\partial n(t, r)}{\partial t} + \nabla \cdot [n(t, r)u(t, r)] = D \Delta n(t, r),$$

where $D = kT/6\pi \nu a$ is the coefficient of molecular (Brownian) diffusion, $\nu$ is the fluid kinematic viscosity, $\rho$ and $T$ are the fluid density and temperature, respectively, $a$ is the radius of a particle, and $k$ is the Boltzmann's constant. Due to the inertia of particles their velocity $u(t, r) \neq \dot{r}(t, r)$, e.g., the field $v(t, r)$ is not divergence free even for $\text{div } u = 0$ (see Ref. [19]). Equation (1) implies conservation of the total number of particles in a closed volume. Consider

$$\Theta(t, r) = n(t, r) - \bar{n},$$

the deviation of $n(t, r)$ from the uniform mean number density of particles $\bar{n}$. Equation for $\Theta(t, r)$ follows from Eq. (1):

$$\frac{\partial \Theta(t, r)}{\partial t} + [v(t, r) \cdot \nabla] \Theta(t, r) = -\Theta(t, r) \text{div } v(t, r) + D \Delta \Theta(t, r).$$

Here we assumed that the mean particle velocity is zero. We also neglected the term $\approx \bar{n} \text{div } v$ describing a source of fluctuations of particles number density. This term does not affect the growth rate of the instability. In the present study we investigate only the effect of self-excitation of the clustering instability, and we do not consider an effect of the source term on the dynamics of fluctuations. The source term $\approx \bar{n} \text{div } v$ is independent of fluctuations of particle number density and causes another type of fluctuations of particle number density which are not directly related to an instability. A mechanism of generation of these fluctuations is related to perturbations of the mean number density of particles by a random divergent velocity field. The magnitude of these fluctuations is much lower than that of fluctuations that are caused by the clustering instability.

In our qualitative analysis of the problem we use Eq. (3) written in a comoving with a cluster reference frame. Formally, this may be done using the Belinicher-L'vov (BL) representation (for details, see Refs. [23, 24]). Let $\xi_0(t_0, r) \equiv \xi(t_0, r)$ be a Lagrangian trajectory, and $\rho_0(t_0, r)$ be an increment of the trajectory of the reference point (located at $r$ at time $t_0$), i.e.,

$$\rho_0(t_0, r) = \int_{t_0}^{t} v[\tau, \xi_0(t, r)] d\tau,$$

$$\xi_0(t_0, r) \equiv \rho_0(t_0, r).$$

By definition $\rho_0(t_0, r) = 0$, $\xi_0(t_0, r_0) = r$ and $r_0$ is a position of a center of a cluster at the “initial” time $t_0 = 0$ (for the brevity of notations hereafter we skip the label $t_0$). Consider a “comoving” reference frame with the position of the origin at $\xi_0(t) = \xi(r_0, t)$. Then BL velocity field $\tilde{v}(r_0, t, r)$ and BL velocity difference $W(r_0, t, r)$ are defined as

$$\tilde{v}(r_0, t, r) = v(t, r + \rho_0(t_0, t)),
\tilde{v}(r_0, t, r) = v[t, r + \rho_0(t_0, t)] - \bar{v}(r_0, t, t_0).$$

Actually the BL representation is very similar to the Lagrangian description of the velocity field. The difference between the two representations is that in the Lagrangian representation one follows the trajectory of every fluid particle $r + \rho_0(r, t_0)$ (located at $r$ at time $t = t_0$), whereas in the BL representation there is a special initial point $r_0$ (in our case the initial position of the center of the cluster) whose trajectory determines the new coordinate system (see Refs. [23, 24]). With time the BL-field $\tilde{v}(r_0, t, r)$ becomes very different from the Lagrangian velocity field. It must be noted that the simultaneous correlators of both, the Lagrangian and the BL-velocity fields, are identical to the simultaneous cor-
relators of the Eulerian velocity \( \mathbf{v}(r,t) \). The reason is that for stationary statistics the simultaneous correlators do not depend on \( t \), and in particular, one can assume \( t = t_0 \).

Similar to Eq. (5), let us introduce BL representation for \( \Theta(t,r) \),

\[
\tilde{\Theta}(r_0|t,r) = \Theta(t,r + \rho_c(r_0|t)).
\]

In BL variables defined by Eqs. (5)–(7), Eq. (3) reads,

\[
\frac{\partial \tilde{\Theta}(r_0|t,r)}{\partial t} + [W(r_0|t,r) \cdot \nabla] \tilde{\Theta}(r_0|t,r) = - \tilde{\Theta}(r_0|t,r) \text{div} W(r_0|t,r) + D \Delta \tilde{\Theta}(r_0|t,r).
\]

The difference between Eqs. (3) and (8) is that Eq. (8) involves only velocity difference (6) in which the velocity \( \mathbf{v}(r_0|t,r_0) \) of the cluster center is subtracted.

### B. Rigid-cluster approximation

Consider qualitatively a time evolution of different statistical moments of the deviation \( \Theta(t,r) \) defined by

\[
\mathcal{M}_q(t) = \langle |\Theta(t,r)|^q \rangle_v,
\]

assuming that at the initial time, \( t = 0 \), the spatial distribution of particles is almost homogeneous, all moments \( \mathcal{M}_q(0) \) are small, where \( \langle \cdot \rangle_v \) denotes the ensemble averaging over random velocity field \( \mathbf{v} \). In order to eliminate the kinematic effect of sweeping of the cluster as a whole we consider Eq. (3) in the BL representation, Eq. (8). Since the simultaneous moments of any field variables in the Eulerian and in the BL-representations coincide, the moments \( \mathcal{M}_q(t) \) can be written as

\[
\mathcal{M}_q(t) = \langle |\tilde{\Theta}(r_0|t,r)|^q \rangle_v.
\]

Our conjecture is that on a qualitative level we can consider the role of each term in the Eq. (8) separately, assuming some reasonable, time-independent, frozen shape \( \theta(x) \) of a distribution \( \tilde{\Theta}(r_0|t,r) \) inside a cluster:

\[
\tilde{\Theta}(r_0|t,r) = A(t) \theta \left( \frac{|r - r_0|}{\ell_{cl}} \right).
\]

Here \( A(t) \) is time-dependent amplitude of a cluster and \( \ell_{cl} \) is the characteristic width of the cluster. Shape function \( \theta(x) \) may be chosen with the maximum equal to 1 at \( x = 0 \) and unit width. Real shapes of various clusters in the turbulent ensemble are determined by a competition of different terms in the evolution equation (8). However, we believe that the particular shapes affect only numerical factors in the expression for the growth rate of clusters and do not affect their functional dependence on the parameters of the problem that is considered in this section.

### 1. Effect of turbulent diffusion

The advective term on the left-hand side (LHS) of Eq. (8) results in turbulent diffusion inside the cluster. This effect may be modeled by renormalization of the molecular diffusion coefficient \( D \) on the right-hand side (RHS) of Eq. (8) by the effective turbulent diffusion coefficient \( D_T \) with a usual estimate of \( D_T \):

\[
D \rightarrow D + D_T, \quad D_T = \ell_{cl} v_{cl} / 3.
\]

Hereafter \( v_{cl} \) is the mean square velocity of particles at the scale \( \ell_{cl} \). Instead of the full Eq. (8) consider now a model equation

\[
\frac{\partial \tilde{\Theta}(r_0|t,r)}{\partial t} = D_T \Delta \tilde{\Theta}(r_0|t,r),
\]

which accounts only for turbulent diffusion. Multiplying Eq. (13) by \( q \tilde{\Theta}^{-1}(r_0|t,r) \) and averaging over random velocity field [see Eq. (10)] we obtain

\[
\partial M_q(t)/\partial t = q \langle |\tilde{\Theta}(r_0|t,r)|^{q-1} D_T \Delta |\tilde{\Theta}(r_0|t,r)| \rangle_w.
\]

Substituting distribution (11) we estimate the Laplacian in Eq. (14) as \(-1/\ell_{cl}^2\). Equations (13) and (14) imply that

\[
\frac{\partial M_q(t)}{\partial t} = -q D_T M_q(t)/\ell_{cl}^2.
\]

The solution of Eq. (15) reads

\[
M_q(t) = M_q(0) \exp[-\gamma_{diff}(q) t],
\]

\[
\gamma_{diff}(q) \sim q D_T / \ell_{cl}^2,
\]

where \( \gamma_{diff}(q) \) denotes a contribution to the damping rate of \( M_q(t) \) caused by turbulent diffusion.

### 2. Effect of particles inertia

In this section we show that the term \(- \tilde{\Theta} \text{div} W \) on the RHS of Eq. (8) can result in an exponential growth of \( M_q(t) \propto \exp[\gamma_{in}(q) t] \), i.e., in the instability. We denoted here the contribution to the growth rate of \( M_q(t) \), caused by the inertia of particles, by \( \gamma_{in}(q) \). In order to evaluate \( \gamma_{in}(q) \) we neglect now in Eq. (8) both, the convective term on the RHS of this equation (i.e., the turbulent velocity difference inside the cluster) and the molecular diffusion term. The resulting equation reads

\[
\frac{\partial \tilde{\Theta}(r_0|t,r)}{\partial t} = - \tilde{\Theta}(r_0|t,r) \text{div} W(r_0|t,r).
\]

The main contribution to the BL-velocity difference \( W(r_0|t,r) \) in the RHS of this equation is due to the eddies with size \( \ell_{cl} \), the characteristic size of the cluster which is of the order of the Kolmogorov length scale. In smaller length scales the velocity divergence correlation function is approximately constant. Denote by \( v_{cl} \) the characteristic velocity of these eddies and by \( \tau_{\text{diff}} \), the corresponding correlation time. In our qualitative analysis we neglect the \( r \).
In our qualitative analysis integrals \( I_n \) in independent random variables. Using the central limit theorem where

\[
\sim \frac{1}{\sqrt{n}} \left( \sum_{i=1}^{n} Y_i - n \bar{Y} \right)
\]

Together with the decomposition (11) this yields the following equation for the cluster amplitude \( A(t) \):

\[ \frac{\partial A(t)}{\partial t} = -A(t)b(t). \]  

The solution of Eq. (19) reads

\[ A(t) = A_0 \exp[-I(t)], \quad I(t) = \int_0^t b(\tau) d\tau. \]  

Integral \( I(t) \) in Eq. (20) can be rewritten as a sum of integrals \( I_n \) over small time intervals \( \tau_0 \),

\[
I(t) = \sum_{n=1}^{\infty} I_n, \quad I_n(t) = \int_{(n-1)\tau_0}^{n\tau_0} b(\tau) d\tau.
\]

In our qualitative analysis integrals \( I_n \) may be considered as independent random variables. Using the central limit theorem we estimate the total integral

\[ I(t) \sim \sqrt{\left( I_n^2 \right)} \sqrt{N \xi}, \quad \left( I_n^2 \right) = \langle b^2 \rangle \tau_0^2, \]

where \( \langle \cdots \rangle \) denotes averaging over turbulent velocity ensemble, \( \xi \) is a Gaussian random variable with zero mean and unit variance, \( N = t/\tau_0 \). Now we calculate

\[ M_q(t) = \int \Theta^q P(\xi) d\xi, \quad P(\xi) = (1/\sqrt{2\pi}) \exp(-\xi^2/2). \]

Therefore, \( M_q(t) = J_q \exp(q^2 S^2 N^2/2) \), where \( S = \tau_0 \sqrt{\langle b^2 \rangle} \).

\[ J_q = (1/\sqrt{2\pi}) \int \exp(-\xi - qS\sqrt{N}/2) d\xi \sim 1. \]

Since the main contribution to the integral \( J_q \) arises from \( \xi \sim qS\sqrt{N} \), the parameter \( q \) cannot be large. In this approximation the \( q \)th moment

\[ M_q(t) = M_q(0) \exp(\gamma_q t), \]

with \( \gamma_q(q) \) being the growth rate of the \( q \)th moment due to the inertia of particles, which is given by

\[ \gamma_q(q) = -\frac{1}{2} \left\langle \tau_q \left[ \text{div} W(r_0|t,r) \right]^2 \right\rangle v^2 q^2. \]  

3. Qualitative picture of the clustering instability

In the preceding sections we estimated the contributions to the growth rate of \( M_q(t) \) due to the turbulent diffusion \( \gamma_d(q) \), Eq. (16), and due to the particles inertia \( \gamma_i(q) \), Eq. (22). The total growth rate may be evaluated as a sum of these contributions:

\[ \gamma_q = \gamma_d(q) + \gamma_i(q), \]

Clearly, the instability is caused by a nonzero value of \( \gamma_s(\text{div} W)^2 \), i.e., by a compressibility of the particle velocity field \( \mathbf{v}(t,r) \).

Compressibility of fluid velocity itself \( \mathbf{u}(t,r) \) (including atmospheric turbulence) is usually negligible, i.e., \( \text{div} \mathbf{u} = 0 \). However, due to the effect of particles inertia their velocity \( \mathbf{v}(t,r) \) does not coincide with \( \mathbf{u}(t,r) \) (see, e.g., Refs. [25–28]). Indeed, the velocity of particles \( \mathbf{v} \) can be determined from the equation of motion for a particle with \( \rho_p > \rho \),

\[ d\mathbf{v}/dt = (\mathbf{u} - \mathbf{v})/\tau_p, \]

where \( \tau_p \) is the characteristic time of coupling between the particle and surrounding fluid (Stokes time),

\[ \tau_p = m_p/6\pi \rho_p a_s^2/9 \rho v, \]

\( m_p \) and \( \rho_p \) are the mass and material density of particles, respectively. Consider incompressible turbulent flow \( \nabla \cdot \mathbf{u} = 0 \). A solution of the equation of motion for particles with a small Stokes time can be written in the form

\[ \mathbf{v} = \mathbf{u} - \tau_p (d\mathbf{u}/dt) + O(\tau_p^2). \]

(see Ref. [25]). Now we calculate the divergence of Eq. (25):

\[ \nabla \cdot \mathbf{v} = -\tau_p \nabla \cdot [(\mathbf{u} \cdot \nabla)\mathbf{u}] + O(\tau_p^2). \]

The Navier-Stokes equation for the fluid yields

\[ \nabla \cdot [(\mathbf{u} \cdot \nabla)\mathbf{u}] = -\Delta P/\rho, \]

where \( P \) is the fluid pressure. The latter equation and Eq. (26) yield \( \nabla \cdot \mathbf{v} \sim \tau_p \Delta P/\rho \) (see Refs. [19,29]).

A degree of compressibility \( \sigma_v \) of the field \( \mathbf{v}(t,r) \), is defined as

\[ \sigma_v = \langle (\text{div} \mathbf{v})^2 \rangle/\langle \| \nabla \times \mathbf{v} \| \rangle \]

Note that parameter \( \sigma_v \) is independent of the scale of the turbulent velocity field. It characterizes a compressible part of the velocity field as a whole. The main contribution to this parameter comes from the scales that are of the order of the Kolmogorov scale \( \eta \). The degree of compressibility \( \sigma_v \) may be of the order of unity [19,29,20]. The fluid flow parameters are: Reynolds number \( Re = L u_T/\nu \), the dissipative scale of turbulence \( \eta = L Re^{-3/4} \), the maximum scale of turbulent motions \( L \), and the turbulent velocity \( u_T \) in the scale \( L \). Now we can estimate \( \sigma_v \) as

\[ \sigma_v \sim (\rho_p/\rho)^2 (a/\eta)^4 = (a/a_s)^4 \]

(see Ref. [20]), where \( a_s \) is a characteristic radius of particles. For \( a \gg a_s \) the dependence \( \sigma_v(a) \) is more complicated.
Therefore, the growth of the second moment $\Phi(t,R) = \langle \Theta(t,r) \Theta(t,r+R) \rangle$. (30)

In this analysis we used stochastic calculus [e.g., Wiener path integral representation of the solution of the Cauchy problem for Eq. (1), Feynman-Kac formula and Cameron-Martin-Girsanov theorem]. The comprehensive description of this approach can be found in Refs. [21,33–36].

We showed that a finite correlation time of a turbulent velocity plays a crucial role in the clustering instability. Notably, an equation for the second moment $\Phi(t,R)$ of the number density of inertial particles comprises spatial derivatives of high orders due to the nonlocal nature of turbulent transport of inertial particles in a random velocity field with a finite correlation time (see Appendix A and Ref. [20]). However, we found that equation for $\Phi(t,R)$ is a second-order partial differential equation at least for two models of a random velocity field:

Model I. The random velocity with Gaussian statistics of the integrals $\int_0^t \mathbf{v}(i',\xi)d\tau'$ and $\int_0^t b(i',\xi)d\tau'$, see Appendix B.

Model II. The Gaussian velocity field with a small yet finite correlation time, see Appendix C.

In both models equation for $\Phi(t,R)$ has the same form,

$$\frac{\partial \Phi}{\partial t} + \hat{L} \Phi(t,R),$$

but with different expressions for its coefficients. The meaning of the coefficients $B(R)$, $U(R)$, and $\hat{D}_{\alpha\beta}(R)$ is as follows:

Function $B(R)$ is determined only by the compressibility of the velocity field and it causes the generation of fluctuations of the number density of inertial particles.

The vector $U(R)$ determines a scale-dependent drift velocity which describes a transfer of fluctuations of the number density of inertial particles over the spectrum. Note that $U(R=0) = 0$ whereas $B(R=0) \neq 0$. For incompressible velocity field $U(R) = 0$, $B(R) = 0$.

The scale-dependent tensor of turbulent diffusion $\hat{D}_{\alpha\beta}(R)$ is also affected by the compressibility.

In very small scales this tensor is equal to the tensor of the molecular (Brownian) diffusion, while in the vicinity of the maximum scale of turbulent motions this tensor coincides with the usual tensor of turbulent diffusion. Tensor $\hat{D}_{\alpha\beta}(R)$ may be written as

$$\hat{D}_{\alpha\beta}(R) = 2D\delta_{\alpha\beta} + D_{\alpha\beta}^T(R),$$

$$D_{\alpha\beta}^T(R) = D_{\alpha\beta}^T(0) - \hat{D}_{\alpha\beta}^T(R).$$

In Appendix B we found that for Model I,

$$B(R) = 2 \int_0^\infty \langle b(0,\xi(r_1|0))b(\tau,\xi(r_2|\tau)) \rangle d\tau,$$

$$U(R) = -2 \int_0^\infty \langle v(0,\xi(r_1|0))b(\tau,\xi(r_2|\tau)) \rangle d\tau.$$
\[ D_{a\beta}^T(R) = 2 \int_0^\infty \langle v_a[0, \xi(r_1|0)] v_\beta[\tau, \xi(r_2|\tau)] \rangle d\tau. \]

For the \( \delta \)-correlated in time random Gaussian compressible velocity field the operator \( \hat{L} \) is replaced by \( \hat{L}_0 \) in the equation for the second moment \( \Phi(t, R) \), where

\[
\hat{L}_0 = B_0(R) + 2 U_0(R) \cdot \nabla + \hat{D}_{a\beta}(R) \nabla_a \nabla_\beta,
\]

\[
B_0(R) = \nabla_a \nabla_\beta \hat{D}_{a\beta}(R),
\]

\[
U_{0,a}(R) = \nabla_\beta \hat{D}_{a\beta}(R)
\]

(for details see Refs. [20,21]). In the \( \delta \)-correlated in time velocity field the second moment \( \Phi(t, R) \) can only decay in spite of the compressibility of the velocity field. The reason is that the differential operator \( \hat{L}_0 = \nabla_a \nabla_\beta \hat{D}_{a\beta}(R) \) is adjoint to the operator \( \hat{L}_0^\dagger = \hat{D}_{a\beta}(R) \nabla_a \nabla_\beta \) and their eigenvalues are equal. The damping rate for the equation

\[
\partial \Phi/\partial t = \hat{L}_0^\dagger \Phi(t, R)
\]

has been found in Ref. [37] for a compressible isotropic homogeneous turbulence in a dissipative range:

\[
\gamma = -\frac{(3 - \sigma_T)^2}{6 \tau_g (1 + \gamma_T) (1 + 3 \sigma_T)}.
\]

Here \( \sigma_T \) is the degree of compressibility of the tensor \( D_{a\beta}(R) \). For the \( \delta \)-correlated in time incompressible velocity field \( (\sigma_T = 0) \) Eq. (35) was derived in Ref. [22]. Thus, for the Kraichnan model of turbulent advection (with a delta correlated in time velocity field) the clustering instability of the 2nd moment does not occur.

A general form of the turbulent diffusion tensor in a dissipative range is given by

\[
D_{a\beta}^T(R) = (C_1 R^2 \delta_{a\beta} + C_2 R_a R_\beta) / \tau_\eta, \]

\[
C_1 = 2(2 + \sigma_T)/3(1 + \sigma_T),
\]

\[
C_2 = 2(2\sigma_T - 1)/3(1 + \sigma_T).
\]

The parameter \( \sigma_T \) is defined by analogy with Eq. (27):

\[
\sigma_T = \frac{\nabla \cdot D_T \cdot \nabla}{\nabla \times D_T \times \nabla} = \frac{\nabla_a \nabla_\beta \hat{D}_{a\beta}(R)}{\nabla_a \nabla_\beta \hat{D}_{a\beta}^T(R)} \epsilon_{aa'\gamma} \epsilon_{\beta\beta'\gamma}. \]

where \( \epsilon_{a\beta\gamma} \) is the fully antisymmetric unit tensor. Equations (27) and (38) imply that \( \sigma_T = \sigma_0 \) in the case of \( \delta \)-correlated in time compressible velocity field. Equations (33) show that for a finite correlation time identities (34) are violated and

\[ B(R) \neq B_0(R), \quad U(R) \neq U_0(R). \]

For a random incompressible velocity field with a finite correlation time the tensor of turbulent diffusion \( D_{a\beta}(R) \) does not occur.

\[
\sigma_T = \frac{\langle (\nabla \cdot \xi)^2 \rangle}{\langle (\nabla \times \xi)^2 \rangle},
\]

where \( \xi(r_1|t) \) is the Lagrangian displacement of a particle trajectory which passes through point \( r_1 \) at \( t = 0 \). Note that Taylor [38] obtained the coefficient of turbulent diffusion for the mean field in the form

\[
D_{T}(R = 0) = \tau^{-1}\langle \xi_a(r_1|t) \xi_a(r_1|t) \rangle.
\]

**B. Clustering instability in Model I**

Let us study the clustering instability for the model of the random velocity with Gaussian statistics of the integrals

\[
\int_0^t v(t', \xi) dt', \quad \int_0^t b(t', \xi) dt',
\]

see Appendix B. In this model Eq. (31) in a nondimensional form reads

\[
\frac{\partial \Phi}{\partial \bar{t}} = \frac{\Phi''}{m(r)} + (U - C_2) r^2 \frac{2 \Phi'}{r} + B \Phi,
\]

\[
1/m(r) = (C_1 + C_2) r^2 + 2/Sc,
\]

where \( U = UR \) and \( Sc = v/D \) is the Schmidt number. For small inertial particles advected by air flow \( Sc \gg 1 \). The nondimensional variables in Eq. (40) are \( r = R/\eta \) and \( \bar{t} = t/\tau_\eta, B \) and \( U \) are measured in the units \( \tau_\eta^{-1} \). Consider a solution of Eq. (40) in two spatial regions.

(a) **Molecular diffusion region of scales.** In this region \( r \ll Sc^{-1/2} \), and all terms \( \ll r^2 \) (with \( C_1 \), \( C_2 \), and \( U \)) may be neglected. Then the solution of Eq. (40) is given by

\[
\Phi(r) = (1 - \alpha r^2) \exp(\gamma_2 \bar{t}),
\]

where

\[
\alpha = Sc(B - \gamma_2 \tau_\eta)/12, \quad B > \gamma_2 \tau_\eta.
\]

(b) **Turbulent diffusion region of scales.** In this region \( Sc^{-1/2} \ll r \ll 1 \), the molecular diffusion term \( \ll 1/Sc \) is negligible. Thus, the solution of Eq. (40) in this region is

\[
\Phi(r) = A_1 r^{-\lambda} \exp(\gamma_2 \bar{t}),
\]

where

\[
\lambda = (C_1 - C_2 + 2U \pm i C_3)/(C_1 + C_2),
\]

\[
C_3^2 = 4(B - \gamma_2 \tau_\eta)(C_1 + C_2) - (C_1 - C_2 + 2U)^2.
\]

Since the total number of particles in a closed volume is conserved,
Note that the parameters \( \sigma_v, \sigma_T \) for \( \sigma_B = \sigma_U = \sigma_v \) in the case of \( Sc = 10^3 \) (curve c), \( Sc = 10^5 \) (curve b), and \( Sc \rightarrow \infty \) (curve a). The dashed line \( \sigma_v = \sigma_T \) corresponds to the \( \delta \)-correlated in time random compressible velocity field.

\[
\int_0^\infty r^2 \Phi(r) dr = 0.
\]

This implies that \( C_s^2 > 0 \), and therefore \( \lambda \) is a complex number. Since the correlation function \( \Phi(r) \) has a global maximum at \( r = 0 \), \( C_s > 2 U \). The latter condition for very small \( U \) yields \( \sigma_f \approx 3 \). For \( R \approx 1 \) the solution for \( \Phi(r) \) decays sharply with \( r \). The growth rate \( \gamma_2 \) of the second moment of particles number density can be obtained by matching the correlation function \( \Phi(r) \) and its first derivative \( \Phi'(r) \) at the boundaries of the above regions, i.e., at the points \( r = Sc^{-1/2} \) and \( r = 1 \). The matching yields \( C_1/2(C_1 + C_2) \approx 2 \pi/\ln Sc \). Thus,

\[
\gamma_2 = \frac{1}{\tau_\eta(1 + 3 \sigma_T)} \left[ \frac{200 \sigma_U(\sigma_T - \sigma_U)}{3(1 + \sigma_U)} - \frac{(3 - \sigma_T)^2}{6(1 + \sigma_T)} \right. \\
- \frac{3 \pi^2(1 + 3 \sigma_T)^2}{(1 + \sigma_T) \ln^2 Sc} + \frac{20(\sigma_B - \sigma_U)}{\tau_\eta(1 + \sigma_B)(1 + \sigma_U)},
\]

where we introduced parameters \( \sigma_B \) and \( \sigma_U \) defined by

\[
B = 20 \sigma_B / (1 + \sigma_B), \quad U = 20 \sigma_U / 3(1 + \sigma_U).
\]

Note that the parameters \( \sigma_B \approx \sigma_U \approx \sigma_v \). For the \( \delta \)-correlated in time random compressible velocity field \( \sigma_B = \sigma_U = \sigma_T = \sigma_v \). Figure 1 shows the range of parameters \( \sigma_v, \sigma_T \) for \( \sigma_B = \sigma_U = \sigma_v \) in the case of \( Sc = 10^3 \) (curve c), \( Sc = 10^5 \) (curve b), and \( Sc \rightarrow \infty \) (curve a). The dashed line \( \sigma_v = \sigma_T \) corresponds to the \( \delta \)-correlated in time random compressible velocity field. This is a limiting line for the curve “a.” Figure 1 demonstrates that even a very small deviation from the \( \delta \)-correlated in time random compressible velocity field results in the instability of the second moment of the number density of inertial particles. The minimum value of \( \sigma_T \) required for the clustering instability is \( \sigma_T = 0.26 \) and a corresponding value of \( \sigma_v = 0.12 \) (see Fig. 1). For smaller values of \( \sigma_v \), the clustering instability can occur, but it requires larger values of \( \sigma_T \).

C. Clustering instability in Model II

In Model II of a random velocity field, i.e., the Gaussian velocity field with a small yet finite correlation time (small \( \tau_\text{ren} \)), the clustering instability occurs when \( \sigma_v > 0.2 \) (see Appendix C). Indeed, the growth rate \( \gamma_2 \) of the second moment of particles number density is determined by equation

\[
\gamma_2 (1 + \tau_\text{ren} \gamma_2)^2 = \frac{B(\sigma_v) Sc^2 - (3 - \sigma_v)^2}{6(1 + \sigma_v)(1 + 3 \sigma_v)} \\
- \frac{8(1 + 3 \sigma_v)}{3(1 + \sigma_v)} \left[ \frac{\pi}{\ln Sc} \right]^2 \frac{1}{\tau_\eta} + \frac{B(\sigma_v)}{1 + \sigma_v},
\]

where \( \sigma_f > 0.2 \) and \( \tau_\text{ren} = \tau_\eta / \sigma_f \) is the Strouhal number, \( Sc = Sc \sigma_f \approx 1 \), \( \tau_\eta = \tau_\eta / \sigma_f \) and

\[
a_1 = \frac{2(19 \sigma_v + 3)}{3(1 + \sigma_v)}, \quad a_2 = \frac{2(3 \sigma_v + 1)}{3(1 + \sigma_v)},
\]

\[
b_1 = -\frac{1}{27(1 + \sigma_v)^2} (12 - 1278 \sigma_v - 3067 \sigma_v^2),
\]

\[
b_2 = \frac{850}{9} \left( \frac{\sigma_v}{1 + \sigma_v} \right)^2,
\]

\[
b_3 = \frac{1}{27(1 + \sigma_v)^2} (36 + 466 \sigma_v + 2499 \sigma_v^2).
\]

For the derivation of Eqs. (43) we assumed that the correlation function \( f_{\alpha \beta}(R) = \langle \psi_{\alpha}(r_1) \psi_{\beta}(r_2) \rangle \) for homogeneous, isotropic, and compressible velocity field is given by

\[
f_{\alpha \beta}(R) = \frac{u_\eta^2}{3} \left( (F + F_c) \delta_{\alpha \beta} + \frac{RF_c}{2} P_{\alpha \beta} + RF_c^* R_{\alpha \beta} \right),
\]

(see Ref. [37]), and in scales \( 0 < R \approx 1 \) incompressible \( F(R) \) and compressible \( F_c(R) \) components of the random velocity field are given by

\[
F(R) = (1 - R^2)/(1 + \sigma_v), \quad F_c(R) = \sigma_v F(R),
\]

in scales \( R \approx 1 \) the functions \( F = F_c = 0 \). Here \( R \) is measured in the units of \( \sigma_f \). The correlation function of the number density of inertial particles can grow
The sufficient condition for the exponential growth of the instability discussed in Ref. [30]). The clustering instability is saturated by nonlinear effects.

Now let us discuss the mechanism of the nonlinear saturation of the clustering instability by using the example of atmospheric turbulence with characteristic parameters: \( \eta \approx 1 \text{ mm}, \; \tau_\eta \approx 0.1 - 0.01 \text{ s} \). A momentum coupling of particles and turbulent fluid is essential when \( m_p \rho_\text{cl}/\rho \), i.e., the mass loading parameter \( \phi = m_p \rho_\text{cl}/\rho \) is of the order of 1 (see, e.g., Ref. [1]). This condition implies that the kinetic energy of fluid \( p(u^2) \) is of the order of the particles kinetic energy \( m_p \rho_\text{cl}(v^2) \), where \( |u| \sim |v| \). This yields

\[
n_\text{cl} \sim a^{-3}(\rho/3\rho_p).
\]  

For water droplets \( \rho_p/\rho \approx 10^3 \). Thus, for \( a = a_\text{a} \approx 30 \mu \text{m} \) we obtain \( n_\text{cl} \approx 10^4 \text{ cm}^{-3} \) and the total number of particles in the cluster of size \( \eta, \; N_\text{cl} \sim \eta^3 n_\text{cl} \sim 10^3 \). This value may be considered as the lower estimate for the “two-way coupling”, when the effect of fluid on particles has to be considered together with the feedback effect of the particles on the carrier fluid. However, it is plausible to expect that turbulence modification by particles’ is governed by the ratio of the particles energy and the total energy of the suspension (rather than the energy of the carrier fluid) and thus by parameter \( \phi/(1 + \phi) \) (rather then by \( \phi \) itself). The latter parameter saturates when \( \phi \to \infty \) and it cannot suppress the clustering instability. Thus we believe that the two-way coupling can only mitigate but not suppress the clustering instability. Only direct collisions between inertial particles cause an increase of the kinematic viscosity of the mixture and damp the clustering instability.

Indeed, a mechanism of the nonlinear saturation of the clustering instability is “four way coupling” when the particle-particle interaction is also important. In this situation the particles collisions result in an effective particle pressure that prevents further increase in concentration. Particle collisions play essential role when during the lifetime of a cluster the total number of collisions is of the order of number of particles in the cluster. The rate of collisions \( J = n_\text{cl}/\tau_\eta \) can be estimated as \( J \approx \pi a^2 n_\text{cl}^2 v_{\text{rel}} \). The relative velocity \( v_{\text{rel}} \) of colliding particles with different but comparable sizes can be estimated as

\[
|v_{\text{rel}}| \sim \tau_p(u \cdot \nabla)u \sim \tau_p u^2/\eta.
\]  

Indeed, the velocity of an inertial particle with radius \( a \) for the small Stokes time \( \tau_p \) is given by

\[
v(a) = u - \tau_p(a)(u \cdot \nabla)u + O(\tau_p^2(a)).
\]

The relative velocity \( v_{\text{rel}} \) of colliding particles with different but comparable sizes \( a_1 \) and \( a_2 \) is given by

\[
|v_{\text{rel}}| = |v(a_1) - v(a_2)| = |\tau_p(a_1) - \tau_p(a_2)| |(u \cdot \nabla)u|.
\]

Assuming that \( |\tau_p(a_1) - \tau_p(a_2)| \sim \tau_p(a_1) \) we obtain Eq. (26). Thus the collisions in clusters may be essential for

\[
n_\text{cl} \sim a^{-3}(\eta/\rho(3\rho_p)), \quad \ell_s \sim a(3a \rho_p/\eta)^{1/3},
\]
where $\ell_s$ is a mean separation of particles in the cluster. For the above parameters ($a = 30 \mu m$) $n_{cl} \sim 3 \times 10^5 \text{ cm}^{-3}$, $\ell_s \sim 5a = 150 \mu m$, and $N_{cl} \sim 300$. Note that the mean number density of droplets in clouds $n_0$ is about $10^2 - 10^3 \text{ cm}^{-3}$. Therefore the clustering instability of droplets in the clouds increases their concentrations in the clusters by the orders of magnitude.

In all our analyses we have neglected the effect of sedimentation of particles in the gravity field which is essential for particles of the radius $a \geq 100 \mu m$. Taking $\ell_s = \eta$ we assumed implicitly that $\tau_p < \tau_\eta$. This is valid (for the atmospheric conditions) if $a \leq 60 \mu m$. Otherwise the cluster size can be estimated as $\ell_s = \eta (\tau_p / \tau_\eta)^{3/2}$.

Our estimates support the conjecture that the clustering instability serves as a preliminary stage for the coagulation of water droplets in clouds leading to the rain formation.

V. DISCUSSION

In this study we investigated the clustering instability of the spatial distribution of inertial particles advected by a turbulent velocity field. The instability results in the formation of clusters, i.e., small-scale inhomogeneities of aerosols and droplets. The clustering instability is caused by a combined effect of the particle inertia and finite correlation time of the velocity field. The finite correlation time of the turbulent velocity field causes the compressibility of the field of Lagrangian trajectories. The latter implies that the number of particles flowing into a small control volume in a Lagrangian frame does not equal the number of particles flowing out of this control volume during a correlation time. This can result in the depletion of turbulent diffusion.

The role of the compressibility of the velocity field is as follows. The divergence of the velocity field of the inertial particles is given by $\text{div} \mathbf{v} = \tau_p \Delta P / \rho$. The inertia of particles results in the fact that particles inside the turbulent eddies are carried out to the boundary regions between the eddies by inertial forces (i.e., regions with low vorticity and high strain rate). For a small molecular diffusivity $\text{div} \mathbf{v} \propto -dn/dt$ [see Eq. (1)]. Therefore, $dn/dt \propto -\tau_p \Delta P / \rho$. Thus there is accumulation of inertial particles (i.e., $dn/dt > 0$) in regions with $\Delta P < 0$. Similarly, there is an outflow of inertial particles from the regions with $\Delta P > 0$. This mechanism acts in a wide range of scales of a turbulent fluid flow. Turbulent diffusion results in the relaxation of fluctuations of particle concentration in large scales. However, in small scales where turbulent diffusion is small, the relaxation of fluctuations of particle concentration is very weak. Therefore the fluctuations of particle concentration are localized in the small scales.

This phenomenon is considered for the case when density of fluid is much less than the material density $\rho_p$ of particles ($\rho \ll \rho_p$). When $\rho \gg \rho_p$ the results coincide with those obtained for the case $\rho \ll \rho_p$ except for the transformation $\tau_p \rightarrow \beta_* \tau_p$, where

$$\beta_* = 2 \left(1 + \frac{\rho}{\rho_p} \right) \frac{\rho_p - \rho}{2 \rho_p + \rho}.$$

For $\rho \gg \rho_p$ the value $dn/dt \propto -\beta_* \tau_p \Delta P / \rho$. Thus there is accumulation of inertial particles (i.e., $dn/dt > 0$) in regions with the minimum pressure of a turbulent fluid since $\beta_* < 0$. In the case $\rho \gg \rho_p$ we used the equation of motion of particles in fluid flow which takes into account contributions due to the pressure gradient in the fluid surrounding the particle (caused by acceleration of the fluid) and the virtual (“added”) mass of the particles relative to the ambient fluid [39].

The particle inertia causes compressibility of particles velocity field. However, a $\delta$-correlated velocity field cannot induce the exponential growth of the second moment of the number density of inertial particles. The reason is that a $\delta$-correlated in time velocity field has a zero memory time. Since the lifetime of eddies in a $\delta$-correlated in time velocity field is infinitely small, the particles do not have enough time to be carried out to the boundaries between eddies. The effect of particle clustering is determined by three competitive processes: the carrying-out of particles to the boundaries between eddies by inertial force [described by $B(R)$-term in Eq. (31)], the scale-dependent turbulent diffusion $\bar{D} \sigma_p(R)$ and the scale-dependent drift velocity $U(R)$ (which describes the transfer of fluctuations of the number density of particles over the spectrum). In a $\delta$-correlated in time velocity field there is a certain relation or constraint [see Eq. (34)] between these processes. A finite correlation time of velocity field violates such symmetry, in particular the finite correlation time affects these three processes in a different manner so that the final effect can cause the exponential growth of the second moment of the number density of particles. In a $\delta$-correlated in time velocity field, there can be only relaxation of the second moment of the number density of particles or a zero damping rate.

The exponential growth of the second moment of a number density of inertial particles due to the small-scale instability can be saturated by the nonlinear effects (see Sec. IV). The excitation of the second moment of a number density of particles requires two kinds of compressibilities: compressibility of the velocity field and compressibility of the field of Lagrangian trajectories. The finite correlation time of velocity field causes compressibility of Lagrangian trajectories even for the incompressible velocity field. Definitely, a compressible velocity field contributes to the compressibility of Lagrangian trajectories. However, the most important effect for the exponential growth of the second moment of the number density of inertial particles is a finite correlation time that violates the symmetry induced by a $\delta$-correlated in time velocity field.

Remarkably, the compressibility of the field of Lagrangian trajectories determines the coefficient of turbulent diffusion [i.e., the coefficient $D_{\sigma_p}(R)$ of the second-order spatial derivative of the second moment of a number density of inertial particles in Eq. (31)]. The compressibility of the field of Lagrangian trajectories causes depletion of turbulent diffusion in small scales even for $\sigma_v = 0$. On the other hand, the compressibility of the velocity field determines a coefficient $B(R)$ of the second moment of a number density of inertial
particles in Eq. (31). This term is responsible for the exponential growth of the second moment of particles.

In this study we considered two models of turbulent velocity field: the random velocity with Gaussian statistics of the Lagrangian trajectories (Model I) and the Gaussian velocity field with a small yet finite correlation time (Model II). These models can be considered as “closure assumptions” and they are not really expected to be exactly satisfied in most of the industrial and atmospheric flows. Remarkably, these two models yield very similar quantitative results for the clustering instability. This allows us to suggest that the clustering is not strongly dependent on the details of the models and statistics. The most important observation is that in these two models a random velocity field has a finite correlation time.

VI. SUMMARY

We showed that the physical reason for the clustering instability in spatial distribution of particles in turbulent flows is a combined effect of the inertia of particles leading to the compressibility of the particle velocity field $v(t,r)$ and the finite velocity correlation time.

The clustering instability can result in a strong clustering whereby a finite fraction of particles is accumulated in the clusters, and in a weak clustering when a finite fraction of particle collisions occurs in the clusters.

The crucial parameter for the clustering instability is a radius of the particles $a$. The instability criterion is $a > a_{cr} = a_\eta$ for which $(\langle (\operatorname{div} v)^2 \rangle)^{1/2} = (\langle |\operatorname{rot} v|^2 \rangle)^{1/2}$. For the droplets in the atmosphere $a_\eta = 30 \mu m$. The growth rate of the clustering instability $\gamma_{cr} = \tau^{-1} a/a_\eta$, where $\tau_\eta$ is the turnover time in the viscous scales of turbulence.

We introduced a new concept of compressibility of the turbulent diffusion tensor caused by a finite correlation time of an incompressible velocity field. For this model of the velocity field, the field of Lagrangian trajectories is not divergence free.

We suggested a mechanism of saturation of the clustering instability—particle collisions in the clusters. An evaluated nonlinear level of the saturation of the droplets number density in clouds exceeds by the orders of magnitude their mean number density.

APPENDIX A: BASIC EQUATIONS IN THE MODEL WITH A RANDOM RENEWAL TIME

In this appendix we derive Eq. (A20) for the simultaneous second-order correlation function $\Phi(t,r)$, which serves as a basis for further analysis in Appendixes B and C under some simplifying model assumptions about the statistics of the velocity field.

1. Exact solution of dynamical equations for a given velocity field

a. Simple case without molecular diffusion

Consider first Eq. (1) for the number density of particles $n(t,r)$ in the case $D = 0$:

\[
\frac{\partial n(t,r)}{\partial t} + \nabla \cdot [n(t,r)v(t,r)] = 0, \quad (A1)
\]

when all particles are transported only by advection. Solution of Eq. (A1) with the initial condition $n(s,r)$ is given by

\[
n(t,r) = G(t,r)n[s,\xi(t,r)], \quad (A2)
\]

where $\xi(t,r)$ is the Lagrangian trajectory of the particle which is located at coordinate $r$ at time $t$. Here we label the particle at present moment of time $t$ and consider a current time $s < t$ as moments in the past. This differs from a usual approach, see Eqs. (4), when particles are labeled at the initial time $t_0$, and a current time $t > t_0$. Therefore in the equations below it is more convenient to redefine Lagrangian displacement $p_l(t,r) = s - t_l(t,r)$. Now Eqs. (4) can be written as

\[
\tilde{p}_{l}(t,r) = \int_{t_0}^{t} v[\tau,\xi(t,r)] d\tau, \quad (A3)
\]

\[
\xi(t,r) = r - \tilde{p}_{l}(t,r). \quad (A4)
\]

The Green function is the functional of $\xi(t,r)$:

\[
G(t,r,s) = \exp \left[ - \int_{s}^{t} b[\tau,\xi(t,r)] d\tau \right], \quad (A5)
\]

\[
b(t,r) = \nabla \cdot v(t,r).
\]

Introduce the shift operator

\[
\exp[\tilde{p}_{l} \cdot \nabla] = 1 - \tilde{p}_{l} \cdot \nabla + \frac{1}{2!} [ - \tilde{p}_{l} \cdot \nabla ]^2 - \cdots, \quad (A6)
\]

which acts as follows:

\[
\exp[\tilde{p}_{l} \cdot \nabla] n(t,r) = n(t,r - \tilde{p}_{l}). \quad (A7)
\]

One can validate relation (A7) by Taylor series expansion of the function $n(t,r - \tilde{p}_{l})$. Now Eq. (A2) can be rewritten as follows:

\[
n(t,r) = G(t,r,s) \exp[\tilde{p}_{l}(t,r) \cdot \nabla] n(s,r), \quad (A8)
\]
b. Molecular diffusion as a Wiener process

Consider now the full Eq. (1) with $D \neq 0$ whereby particles are transported by both, fluid advection and molecular diffusion. It was found by Wiener (see, e.g., Ref. [33]) that Brownian motion (molecular diffusion) can be described by the Wiener random process $w(t)$ with the following properties:

$$\langle w(t) \rangle_w = 0, \quad \langle w_i(t + \tau) w_j(t) \rangle_w = \tau \delta_{ij}. \quad (A9)$$

Here $\langle \cdots \rangle_w$ denotes the mathematical expectation over the statistics of the Wiener process. Introduce the Wiener trajectory $\xi_{w}(t,r)s$ (which usually is called the Wiener path) and the Wiener displacement $\mathbf{\rho}_{w}(t,r)s$ as follows:

$$\xi_{w}(t,r)s \equiv r - \mathbf{\rho}_{w}(t,r)s, \quad (A10)$$

$$\mathbf{\rho}_{w}(t,r)s = \int_{s}^{t} \mathbf{v}[\tau, \xi_{w}(t,r)\tau]d\tau + \sqrt{2Dw(t-s)}. \quad (A11)$$

Comparison of this formula with Eqs. (A3) shows that in the limit $D \rightarrow 0$, $\xi_{w}(t,r)s \rightarrow \xi_{0}(t,r)s$ and $\mathbf{\rho}_{w}(t,r)s \rightarrow \mathbf{\rho}_{0}(t,r)s$.

In Refs. [35,36] it was shown that solution of Eq. (1) (with $D \neq 0$) can be written as solution (A8) of Eq. (A1) (with $D = 0$) by replacement $\mathbf{\rho}_{0}(t,r)s \rightarrow \mathbf{\rho}_{w}(t,r)s$ and then averaging over the statistics of the Wiener processes (A9):

$$n(t,r) = \langle G(t,r,s) \exp[-\mathbf{\rho}_{w}(t,r)s \cdot \mathbf{\nabla}] \rangle_w n(s,r). \quad (A12)$$

2. Two-step averaging over velocity statistics

a. Model of a random velocity field

Note that Eq. (A11) is a solution of Eq. (1) at a given realization of the random velocity field. Our next goal is to determine the simultaneous correlation functions:

$$\bar{n}(t) = \langle \langle n(t,r) \rangle \rangle_w, \quad (A13)$$

$$\Phi(t,r_2-r_1) = \langle \langle n(t,r_1)n(t,r_2) \rangle \rangle_w - \bar{n}^2(t), \quad (A14)$$

averaged over the stationary, space homogeneous statistics of turbulent velocity field, where $\langle \langle \cdots \rangle \rangle_w$ denotes this averaging. Since the initial distribution $n(t_0,r)$ is assumed to be homogeneous in space, $n(t)$ is independent of spatial coordinate, and $\Phi(t,r_2-r_1)$ depends only on the difference $R = r_2 - r_1$.

In order to simplify the averaging procedure (A12) we consider a model of random velocity field that fully loses memory at some instants of renewal $\tau_j$. For $t_1$ and $t_2$ inside a renewal interval $[t_1 \leq t_2 \leq t_1 \tau_{j+1}]$ the velocity pair correlation function is defined as:

$$\mathcal{F}^{ab}(t_2-t_1, r_2-r_1) = \langle v_{a}(t_1,r_1) v_{b}(t_2,r_2) \rangle, \quad (A15)$$

where $\langle \langle \cdots \rangle \rangle_w$ denotes averaging over “intrinsic statistics” of the velocity field. In our model the velocity fields before and after renewals are statistically independent. The interval between the renewal instants $\tau_j$ may be the same or randomly distributed, say with the Poisson statistics. In the latter case the full averaging $\langle \langle \cdots \rangle \rangle_w$ may be considered as a two-stage procedure. First one calculates $\langle \langle \cdots \rangle \rangle_w$ and then averages over the statistics of the renewal time $\tau_{\text{ren}}$, which is denoted as $\langle \langle \cdots \rangle \rangle_{\text{ren}}$.

$$\langle \langle \cdots \rangle \rangle_w = \langle \langle \cdots \rangle \rangle_{\text{ren}}. \quad (A16)$$

For the Poisson statistics of $\tau_j$,

$$\mathcal{F}^{ab}(t_2-t_1, r_2-r_1) = \langle \langle v_{a}(t_1,r_1) v_{b}(t_2,r_2) \rangle \rangle_w$$

$$= \mathcal{F}^{ab}(t_2-t_1, r_2-r_1) \times \exp \left( -|t_2-t_1|/\tau_{\text{ren}} \right), \quad (A17)$$

where $\tau_{\text{ren}}$ is the mean renewal time. It would be useful to define the correlation time of the function $\mathcal{F}^{ab} \beta$ as follows:

$$\tau_{\text{v}}(\mathcal{R}) = \int \mathcal{F}^{ab}(\tau, \mathcal{R}) \mathcal{d}\tau / \mathcal{F}^{ab}(0, \mathcal{R}). \quad (A18)$$

Certainly this model of the random velocity field cannot be considered as universal. However, it reproduces important features of some flows (see, e.g., Ref. [40]).

b. Averaging procedure

Our model involves three random processes: (1) The Wiener random process that describes Brownian (molecular) diffusion, (2) Poisson process for a random renewal time, and (3) the random velocity field between the renewals.

Equation (A11) presents $n(t,r)$ after the first step, i.e., it describes the number density at a given realization of a velocity field. Using Eq. (A11) we obtain

$$n(t,r_1)n(t,r_2) = \langle G(r_1)G(r_2) \exp[\xi'(r_1) \cdot \nabla] \rangle \times$$

$$\times \langle \langle n(s,r_1)n(s,r_2) \rangle \rangle_w, \quad (A19)$$

where $\nabla_1 = \partial / \partial r_1$ and $\nabla_2 = \partial / \partial r_2$ and $\langle \langle \cdots \rangle \rangle_w$ denotes averaging over two independent Wiener processes determining two Wiener paths. Hereafter for simplicity we use the following notations: $G(r) = G(t,r,s)$ and $\xi'(r) = -\mathbf{\rho}_{w}(t,r)s$.

Now we average Eq. (A17) over a random velocity field for a given realization of a Poisson process:

$$\bar{n}(t) = \langle \langle n(t,r_1)n(t,r_2) \rangle \rangle_w - \bar{n}^2(t)$$

$$= \langle \langle G(r_1)G(r_2) \exp[\xi'(r_1) \cdot \nabla] \rangle$$

$$\times \langle \langle n(s,r_1)n(s,r_2) \rangle \rangle_w \rangle_{\text{v}} \times \Phi(t_0,r_1-r_2). \quad (A20)$$

Here the time $t_0$ is the last renewal time before time $t$ and $t' = t-t_0$ is a random variable. Now we omit the source term $[\langle \langle G(r_1)G(r_2) \rangle \rangle_w - 1] \bar{n}^2$ in Eq. (A20) (which is caused by the mean number density of particles in a divergent velocity field) and we use the relation that is valid for homogeneous turbulence, $\nabla_1 \bar{n}^2 = \nabla_2 \bar{n}^2 = 0$. The reason is that in the
present study we investigate only the effect of self-excitation of the clustering instability, and we do not consider an effect of the source term on the dynamics of fluctuations. The source term is independent of fluctuations of particle number density and causes another type of fluctuation of particle number density which is not directly related to an instability. A mechanism of the generation of these fluctuations is related to perturbations of the mean number density of particles by a random divergent velocity field. The magnitude of these fluctuations is much smaller than that of fluctuations caused by the clustering instability.

Thus, averaging of the functions

\[ G(r_1)G(r_2)\exp[\xi'(r_1) \cdot \nabla_1 + \xi'(r_2) \cdot \nabla_2] \]

and \( \tilde{\Phi}(t_0,r_1-r_2) \) is decoupled into two time intervals because the first function is determined by the velocity field after the renewal while the second function \( \tilde{\Phi}(t_0,r_1-r_2) \) is determined by the velocity field before renewal. Now we take into account that for the Poisson process any instant can be chosen as the initial instant so that the time for the next renewal is distributed exponentially. We average Eq. (A18) over the random renewal time. The probability density \( p(t) \) of a random renewal time is given by

\[ p(t) = \tau_{\text{ren}}^{-1} \exp(-t/\tau_{\text{ren}}). \]  

(A19)

Thus the resulting averaged equation for “fully” averaged correlation function \( \Phi(t,R) = \tilde{\Phi}(t,R) \tau_{\text{ren}}^{-1} \) defined by Eq. (A12), assumes the following form:

\[ \Phi(t,R) = \tau_{\text{ren}}^{-1} \int_0^t \tilde{P}(\tau,R) \Phi(t-\tau,R) \exp(-\tau/\tau_{\text{ren}}) d\tau \]

\[ + \exp(-t/\tau_{\text{ren}}) \tilde{P}(t,R) \Phi_0(R). \]  

(A20)

The first term in Eq. (A20) describes the case where there is at least one renewal of the velocity field during the time \( t \) (i.e., the Poisson event), whereas the second term describes the case where there is no renewal during the time \( t \). Here \( \Phi_0(R) = \Phi(t=0,R) \) and

\[ \tilde{P}(t,R) = \langle \langle G(r_1)G(r_2)\exp[\xi'(r_1) \cdot \nabla_1 + \xi'(r_2) \cdot \nabla_2]\rangle\rangle_e \]

\[ = \langle \langle g(r_1) + g(r_2) + \xi'(r_1) \cdot \nabla_1 + \xi'(r_2) \cdot \nabla_2 \rangle\rangle_{\text{ww}} e \].  

(A21)

where \( G(r) = \exp[g(r)] \). Equation (A20) is simplified in Appendices B and C under the additional assumptions about the velocity field statistics.

c. Properties of the function \( G(r) \)

Averaging Eq. (A11) over a random velocity field, we obtain equation for the mean number density of particles. In \( k \) space for a homogeneous turbulence, this equation is given by

\[ \tilde{n}(t,k) = \mathcal{P}(t-s,-k) \tilde{n}(s,k), \]  

(A22)

where

\[ \mathcal{P}(t-s,-k) = \langle \langle \exp[ik \cdot \xi'(r)] G(r) \rangle\rangle_e. \]  

(A23)

Equations (A22) and (A23) were derived in Ref. [35] [see Eqs. (17) and (18) in Ref. [35]]. The operator \( \mathcal{P}(t-s,-k) \) is independent of \( r \) due to the assumption about the homogeneous turbulence. Note that \( \tilde{n}(t,k=0) = (2\pi)^{-3} \int \tilde{n}(t,r) dr = N \) is the total number of particles that are conserved in a closed volume. Thus, the total number of particles is given by

\[ \tilde{n}(t,k=0) = \bar{n}(s,k=0) = N. \]  

(A24)

On the other hand,

\[ \mathcal{P}(t-s,k=0) = \langle \langle G(r) \rangle\rangle_e \]  

(A25)

[see Eq. (A23)]. Thus, Eqs. (A22), (A24), and (A25) yield

\[ \langle \langle G(r) \rangle\rangle_e = 1. \]  

(A26)

APPENDIX B: VELOCITY FIELD WITH GAUSSIAN LAGRANGIAN TRAJECTORIES

Consider the model of a random velocity field where Lagrangian trajectories, i.e., the integrals \( \int \mathbf{v}(\mu, \xi) d\mu \) and \( \int \mathbf{b}(\mu, \xi) d\mu \) have Gaussian statistics. Now we use an identity

\[ \langle \langle \exp[g(r)] \rangle\rangle_e = \exp[\langle \langle G(r) \rangle\rangle_e]. \]  

(B1)

\[ G(r) = \frac{1}{2} \langle \langle \tilde{g}^2 \rangle\rangle_e + \tilde{g}, \]  

(B2)

where \( g = \tilde{g} + \tilde{\mathcal{G}} \) is a Gaussian random variable with a mean value \( \tilde{g} = \langle \langle g \rangle\rangle_e \). Here, for simplicity of notations, we omitted arguments in the functions \( G \) and \( g \). Since

\[ \langle \langle \exp[g(r)] \rangle\rangle_e = \langle \langle G(r) \rangle\rangle_e = 1, \]  

(B3)

we obtain \( \exp[\langle \langle G(r) \rangle\rangle_e] = 1 \), i.e., \( G(r) = 0 \) [see Eqs. (B1)–(B3) and (A26)].

Now we calculate \( \tilde{P}(\mu, R) = \langle \langle \exp[g(r_1) + g(r_2) + \xi'(r_1) \cdot \nabla_1 + \xi'(r_2) \cdot \nabla_2] \rangle\rangle_e \) in Eq. (A21), using identity (B1). The result is given by

\[ \tilde{P}(\mu, R) = \exp[\langle \langle G(r_1) + G(r_2) + \mu \hat{\mathcal{G}} \rangle\rangle_e], \]  

(B4)

where

\[ \hat{\mathcal{G}} = B(R) + 2 U_\alpha(R) \nabla_\alpha + \hat{D}_{\alpha\beta}(R) \nabla_\alpha \nabla_\beta, \]

\[ \mu B(R) = \langle \langle g(r_1) g(r_2) \rangle\rangle_{\text{ww}} e, \]

\[ \mu U_\alpha(R) = -\langle \langle \xi'(r_1) g(r_2) \rangle\rangle_{\text{ww}} e, \]  

(B5)

\[ \hat{D}_{\alpha\beta}(R) = D_{\alpha\beta}(0) - D_{\alpha\beta}(R), \]
When correlation time correlation of the Eulerian velocity calculated at Lagrangian trajectories is much less than the current time and \( \tau_{ren} \), the correlation functions (B5) are given by

\[
B(R) = 2 \int_0^\infty \left\langle \left\langle b[0, \xi_\alpha(r_1)]b[\mu', \xi_\beta(r_2)] \right\rangle_{\omega_\alpha} \right\rangle_{\omega_\beta} d\mu',
\]

\[
U_{ab}(R) = -2 \int_0^\infty \left\langle \left\langle v_a[0, \xi_\alpha(r_1)]b[\mu', \xi_\beta(r_2)] \right\rangle_{\omega_\alpha} \right\rangle_{\omega_\beta} d\mu',
\]

\[
D_{ab}(R) = 2 \int_0^\infty \left\langle \left\langle v_b[0, \xi_\alpha(r_1)]v_b[\mu', \xi_\beta(r_2)] \right\rangle_{\omega_\alpha} \right\rangle_{\omega_\beta} d\mu',
\]

where we used a relation

\[
\left\langle \left\langle \int_0^\mu a_\alpha(\mu', r_1) d\mu' \int_0^\mu c_\beta(\mu'', r_2) d\mu'' \right\rangle \right\rangle_{\omega} = 2\mu \int_0^\infty \left\langle (a_\alpha(0, r_1)c_\beta(\mu', r_2))_{\omega} \right\rangle d\mu'.
\]

In Eq. (B7) for \( B(R) \), the function \( b[\tau, \xi_\alpha(r)] \) is the divergence of the Eulerian velocity calculated at Lagrangian trajectory, i.e.,

\[
b[\tau, \xi_\alpha(r)] = \frac{\partial u_i}{\partial r_i} \bigg|_{r=\xi_\alpha(r)}.
\]

The function \( b[\tau, \xi_\alpha(r)] \) is different from the divergence \( b_L[\tau, \xi_\alpha(r)] \) of the Lagrangian velocity, i.e.,

\[
b_L[\tau, \xi_\alpha(r)] = \frac{\partial v_i}{\partial r_i} \bigg|_{\tau = \xi_\alpha(r)}.
\]

In a \( \delta \)-correlated in time velocity field \( b[\tau, \xi_\alpha(r)] \) is different from \( b_L[\tau, \xi_\alpha(r)] \) whereas for a random velocity field with a finite correlation time \( b[\tau, \xi_\alpha(r)] \neq b_L[\tau, \xi_\alpha(r)] \). The iner-
tia of particles causes compressibility of the Eulerian velocity. On the other hand, the finite correlation time of a random velocity field causes a compressibility of the field of Lagrangian trajectories (which determine the turbulent diffusion tensor) even for incompressible velocity field. Eq. (B6) allows to rewrite Equation (A20) as

\[
\Phi(t,R) = \frac{1}{\tau_{ren}} \left[ \int_0^t \exp(\mu \hat{L}_i) d\mu \right] \Phi(t,R) + \exp(t \hat{L}_i) \Phi(t,R),
\]

where

\[
P(R,R_0) = \exp(\mu \hat{L}) - \frac{1}{\tau_{ren}}.
\]

To derive Eq. (B10) we used the following identity

\[
\Phi(t - \mu, R) = \exp \left( -\mu \frac{\partial}{\partial t} \right) \Phi(t, R),
\]

which follows from the Taylor expansion

\[
f(t + \tau) = \sum_{m=1}^\infty \left( \tau \frac{\partial}{\partial t} \right)^m f(t) \exp \left( \tau \frac{\partial}{\partial t} \right) f(t).
\]

In particular,

\[
\Phi(t, R) = \Phi(t - \tau, R) = \exp \left( -\tau \frac{\partial}{\partial t} \right) \Phi(t, R).
\]

Evaluating the integral in Eq. (B10) we obtain

\[
[ \exp(t \hat{L}_i) - 1 ](\hat{L}_i + \tau_{ren}) \Phi(t, R) = 0.
\]

Here we used the commutativity relation

\[
\hat{L}_i \exp(t \hat{L}_i) = \exp(t \hat{L}_i) \hat{L}_i.
\]

Thus, finally

\[
\frac{\partial \Phi}{\partial t} = [B(R) + 2U(R) \cdot \nabla + \hat{D}_{ab}(R) \nabla_a \nabla_b] \Phi(t, R).
\]

Note that in the limit \( \tau_{ren} \rightarrow \infty \), Eq. (B15) describes the evolution of \( \Phi(t, R) \) in the model of the random velocity field without renewals.

**APPENDIX C: GAUSSIAN VELOCITY FIELD WITH A SMALL YET FINITE CORRELATION TIME**

Here we consider a random Gaussian velocity field with a small \( \tau_{ren} \). Using Eq. (B12) we rewrite Eq. (A20) in the form

\[
\left\{ \frac{1}{\tau_{ren}} \int_0^t \hat{P}(\tau, R) \exp \left( -\frac{\tau}{\tau_{ren}} \hat{M} \right) d\tau \right\} \Phi(t, R) = 0.
\]

where \( \hat{M} = 1 + \tau_{ren}(\partial / \partial t) \) and we neglected the last term in Eq. (A20) since \( \tau \gg \tau_{ren} \). Expanding the function \( \hat{P}(\tau, R) \) in Taylor series in the vicinity of \( \tau = 0 \) we obtain

\[
\left\{ \sum_{k=0}^\infty \frac{\tau^k}{\tau_{ren}^k} \frac{\partial^k \hat{P}(\tau, R)}{\partial \tau^k} \right\} \frac{\hat{M}^{-(k+1)}}{\tau_{ren}^{(k+1)-1}} \Phi(t, R) = 0.
\]

where we used the following formula:

\[
\int_0^t t^k \exp \left( -\frac{\tau}{\tau_{ren}} \hat{M} \right) d\tau = k! \frac{\tau_{ren}^{k+1}}{\hat{M}^{(k+1)}}.
\]
Neglecting the terms $\sim O(\tau_{\text{ren}}^{-5})$ in Eq. (C2) we obtain
\[
\ddot{M}^2 \frac{\partial \Phi(t, R)}{\partial t} = \tau_{\text{ren}} \left[ \left( \frac{\partial^2 \hat{P}(\tau, R)}{\partial \tau^2} \right)_{\tau=0} + \frac{\tau_{\text{ren}}^2}{\tau_{\text{ren}}^2} \left( \frac{\partial^2 \hat{P}(\tau, R)}{\partial \tau^4} \right)_{\tau=0} \right] \Phi(t, R), \tag{C3}
\]
since the expansion of the operator $\hat{P}(\tau, R)$ into Taylor series (for small $\tau$) for a random Gaussian velocity field has only even powers of $\tau$. Thus, the equation for the correlation function $\Phi(t, R)$ is given by
\[
\ddot{M}^2 \frac{\partial \Phi(t, R)}{\partial t} = [B(R) + 2U(R) \cdot \nabla + \hat{D}_{\alpha\beta}(R) \nabla_\alpha \nabla_\beta] \Phi, \tag{C4}
\]
where
\[
\hat{D}_{\alpha\beta}(R) = \frac{1}{2 \tau_{\text{ren}}} \langle \langle \xi_{\alpha} \xi_{\beta} G(r_1) G(r_2) \rangle_{ww} \rangle_v, \tag{C5}
\]
\[
U_\alpha(R) = -\frac{1}{\tau_{\text{ren}}} \langle \langle g'(r_2) \xi_\alpha(r_1) \rangle_{ww} \rangle_v + \frac{1}{2 \tau_{\text{ren}}} \langle \langle g'(r_1) g'(r_2) \xi_\alpha \rangle_{ww} \rangle_v, \tag{C6}
\]
\[
B(R) = \frac{1}{\tau_{\text{ren}}} \langle \langle g'(r_1) g'(r_1) \rangle_{ww} \rangle_v. \tag{C7}
\]
Here, for the homogeneous turbulent velocity field [21],
\[
\mathbf{\tilde{\xi}} = \mathbf{\xi}'(r_2) - \mathbf{\xi}'(r_1), \quad \nabla = \partial / \partial R, \quad G = G + g',
\]
\[
\langle \langle g' \rangle_{ww} \rangle_v = 0, \quad \tilde{G} = \langle \langle G \rangle \rangle_v = 1.
\]
Using the expansion of $\mathbf{\tilde{\xi}}(\tau_{\text{ren}} \mathbf{r})$ and $g' [\tau_{\text{ren}} \mathbf{\xi}(\mathbf{r})]$ into Taylor series of a small time $\tau_{\text{ren}}$ after the lengthy algebra, we obtain
\[
\hat{D}_{\alpha\beta}(R) = 2D \delta_{\alpha\beta} + 2\tau_{\text{ren}} f_{\alpha\beta}(R) + \text{Sr}^2 Q_{\alpha\beta}(R), \tag{C8}
\]
\[
Q_{\alpha\beta}(R) = 3[(\nabla_\mu f_{\alpha\mu})(\nabla_\nu f_{\beta\nu}) - \tilde{f}_{\mu\nu} \nabla_\mu \nabla_\nu f_{\alpha\beta}] + 24A_{\alpha\beta} + 12(A_{\mu} \nabla_\mu f_{\alpha\beta} - \tilde{f}_{\alpha\beta} \nabla_\mu A_{\mu} - 20f_{\alpha\beta} \nabla_\mu A_{\mu}), \tag{C9}
\]
\[
U_\alpha(R) = -2\tau_{\text{ren}} [A_\alpha - \text{Sr}^2 ((\nabla_\nu A_\mu)(\nabla_\lambda f_{\alpha\nu}) + 10A_\nu \nabla_\mu A_\alpha + 12A_\lambda \nabla_\mu A_\mu), \tag{C10}
\]
\[
B(R) = -2\tau_{\text{ren}} [(\nabla_\mu A_\mu + \text{Sr}^2 ((\nabla_\nu A_\mu)(\nabla_\lambda f_{\alpha\nu}) - 6(\nabla_\mu f_{\alpha\mu})^2)], \tag{C11}
\]
\[
A_\alpha = \nabla_\beta f_{\beta\alpha}, \quad \tilde{f}_{\alpha\beta} = f_{\alpha\beta}(0) - f_{\alpha\beta}(R), \quad f_{\alpha\beta}(R) = \langle \langle v_{\alpha}(r_1) v_{\beta}(r_2) \rangle \rangle_v,
\]
and $\text{Sr} = \tau_{\text{ren}} / \tau_\eta$ is the Strouhal number. In these calculations we neglected the small terms $\sim O(\text{Sr}^6 R^4)$ in our analysis. Our analysis showed that the neglected small terms do not affect the growth rate of the clustering instability. In Eqs. (C9)–(C11) we assumed that the correlation function $f_{\alpha\beta}$ for homogeneous, isotropic, and compressible velocity field is given by Eq. (45), and in scales $0<\text{Sr} \ll 1$ incompressible $F(R)$ and compressible $F_\epsilon(R)$ components of the random velocity field are given by
\[
F(R) = (1 - R^2)/(1 + \sigma_v), \quad F_\epsilon(R) = \sigma_v F(R).
\]
in scales $\text{Sr} \ll 1$ the functions $F = F_\epsilon = 0$. Here $R$ is measured in the units of $\eta$. Turbulent diffusion tensor $D_{\alpha\beta}(R)$ is determined by the field of Lagrangian trajectories $\mathbf{\xi}$ [see Eq. (C5)]. Due to the finite correlation time of the random velocity, the field of Lagrangian trajectories $\mathbf{\xi}$ is compressible even if the velocity field is incompressible ($\sigma_v = 0$). Indeed, for $\sigma_v = 0$ we obtain
\[
\langle \langle (\nabla \cdot \mathbf{\xi})^2 \rangle \rangle_v = \frac{20}{3} \text{Sr}^4.
\]
Using Eqs. (C8)–(C11) we calculated the functions $\hat{D}_{\alpha\beta}(R)$, $U_\alpha(R)$ and $B(R):
\]
\[
\hat{D}_{\alpha\beta}(R) = [2\tilde{D} + R^2 (a_3 + \text{Sr}^2 b_6)] \delta_{\alpha\beta} + R^2(a_4 + \text{Sr}^2 b_4) R_{\alpha\beta}, \tag{C12}
\]
\[
U_\alpha(R) = -R_{\alpha} (a_5 + \text{Sr}^2 b_3), \tag{C13}
\]
\[
B = a_6 + \text{Sr}^2 b_2, \tag{C14}
\]
where $b_2 = -\frac{11}{37} b_5$, $\tilde{D} = D/(\tau_{\text{ren}}^2 \eta^2)$, and
\[
a_5 = -\frac{20\sigma_v}{3(1 + \sigma_v)} = -\frac{a_2}{3}, \quad a_3 = \frac{2\sigma_v + 4}{3(1 + \sigma_v)},
\]
\[
a_4 = \frac{4\sigma_v - 2}{3(1 + \sigma_v)}, \quad b_5 = -\frac{2350}{27} \left( \frac{\sigma_v}{1 + \sigma_v} \right)^2,
\]
\[
b_6 = \frac{12 + 872\sigma_v + 433\sigma_v^2}{27(1 + \sigma_v)^2}, \quad b_3 = \frac{2(12 - 203\sigma_v + 1033\sigma_v^2)}{27(1 + \sigma_v)^2}.
\]
We will show here that the combined effect of the inertia of particles ($\sigma_v \neq 0$) and finite correlation time of the particles’ velocity field ($\text{Sr} \neq 0$) results in the excitation of the clustering instability whereby under certain conditions there is a self-excitation of the second moment of the number density...
of inertial particles. This instability causes the formation of small-scale inhomogeneities in the spatial distribution of inertial particles.

The equation for the second-order correlation function for the number density of inertial particles reads

$$
\hat{M} \left[ \frac{\partial^2 \Phi(t, R)}{\partial t^2} - \frac{\partial \Phi}{\partial t} + \frac{\partial^2 \Phi}{\partial R^2} \right] = \frac{m(R)}{2 \lambda(R)} \frac{\partial^2 \Phi}{\partial R^2} + B \Phi
$$

where $\hat{M}$ is the number density of inertial particles reads [see Eqs. (C14)], where the time $t$ is measured in units of $\tau_\eta = \tau_\eta/\dot{S}_c$, and

$$
\Phi' = \frac{\partial \Phi}{\partial R}, \quad \Phi'' = \frac{\partial^2 \Phi}{\partial R^2}, \quad m = \frac{2(1 + X^2)}{\dot{S}_c},
$$

$$
\lambda = \frac{2[2 + X^2(1 + 2 C)]}{R \dot{S}_c}, \quad C = \frac{a_1 + S \dot{S}_c b_1}{4 \beta},
$$

$$
\beta = \frac{a_2 + S \dot{S}_c b_2}{2}, \quad \lambda(R) = \sqrt{\dot{S}_c \beta R}, \quad R = |r_2 - r_1|,
$$

$$
a_1 = \frac{2(19 \sigma_\eta + 3)}{3(1 + \sigma_\eta)}, \quad a_2 = \frac{2(3 \sigma_\eta + 1)}{3(1 + \sigma_\eta)},
$$

$$
b_1 = \frac{1}{27(1 + \sigma_\eta)^2} (12 - 1278 \sigma_\eta - 3067 \sigma_\eta^2),
$$

$$
b_3 = \frac{1}{27(1 + \sigma_\eta)^2} (36 + 466 \sigma_\eta + 2499 \sigma_\eta^2),
$$

where $\dot{S}_c = \dot{S}_c \dot{S}_c > 1$. In order to obtain a solution of Eq. (C15), we use a separation of variables, i.e., we seek for a solution in the following form:

$$
\Phi(t, R) = \Phi(R) \exp(\gamma_2 t),
$$

whereby $\gamma_2$ is a free parameter that is determined using the boundary conditions

$$
\Phi(R = 0) = 1, \quad \Phi(R \rightarrow \infty) = 0.
$$

Here $\gamma_2$ is measured in units of $1/\tau_\eta$. Since the function $\Phi(t, R)$ is a two-point correlation function, it has a global maximum at $R = 0$ and therefore satisfies the conditions

$$
\Phi'(R = 0) = 0, \quad \Phi''(R = 0) < 0,
$$

$$
\Phi(R = 0) > |\dot{\Phi}(R > 0)|.
$$

Then Eq. (C15) yields

$$
\Gamma \dot{\Phi}(R) = \frac{1}{m(R)} \Phi'' + \lambda(R) \dot{\Phi}' + B \dot{\Phi},
$$

where $\Gamma = \gamma_2 (1 + S \dot{S}_c \gamma_2)^2$. Equation (C16) has an exact solution for $0 < R < 1$:

$$
\dot{\Phi}(X) = S(X) X(1 + X^2)^{\mu_2},
$$

$$
S(X) = \text{Re}[A_1 P^{(i)}_\kappa(iX) + A_2 Q^{(i)}_\kappa(iX)],
$$

where $P^{(i)}_\kappa(Z)$ and $Q^{(i)}_\kappa(Z)$ are the Legendre functions with the imaginary argument

$$
Z = iX, \quad \mu = \frac{3}{2}, \quad \xi = -\frac{1}{2} \pm \sqrt{C^2 - \kappa^2}, \quad \kappa = \frac{B - \Gamma}{2 \beta}.
$$

Solution of Eq. (C15) can be analyzed using asymptotics of the exact solution (C17). This asymptotic analysis is based on the separation of scales (see, e.g., Refs. [34,37]). In particular, the solution of Eq. (C15) has different regions where the form of the functions $m(R)$ and $\lambda(R)$ are different. The functions $\Phi(R)$ and $\dot{\Phi}'(R)$ in these different regions are matched at their boundaries in order to obtain continuous solution for the correlation function. Note that the most important part of the solution is localized in small scales (i.e., $R \ll 1$). Using the asymptotic analysis of the exact solution for $X \gg 1$ allowed us to obtain the necessary conditions for a small-scale instability of the second moment of a number density of inertial particles. The results obtained by this asymptotic analysis are presented below.

The solution (C17) has the following asymptotics: for $X \ll 1$ (i.e., in the scales $0 \ll R \ll 1/\sqrt{\dot{S}_c}$) the solution for the second moment $\Phi$ is given by

$$
\dot{\Phi}(X) = \{1 - (\kappa/6)[X^2 + O(4X^2))].
$$

For $X \gg 1$ (i.e., in the scales $1/\sqrt{\dot{S}_c} \ll R \ll 1$) the function $\Phi$ is given by

$$
\dot{\Phi}(X) = \text{Re}[\mu X^{-\frac{1}{2}} \sqrt{\frac{C^2 - \kappa^2}}].
$$

For $C^2 - \kappa < 0$ the second-order correlation function for a number density of inertial particles $\Phi$ is given by

$$
\dot{\Phi}(R) = A_3 R^C \cos(\nu_1 \ln R + \varphi), \quad \nu_1 = \sqrt{\kappa - C^2},
$$

where $C > 0$ and $\varphi$ is the argument of the complex constant $A$. For $R \gg 1$ the second-order correlation function for the number density of inertial particles is given by

$$
\dot{\Phi}(R) = (A_4 / R) \exp(-R \sqrt{3\Gamma/2}),
$$

where $\Gamma > 0$. Since the total number of particles in a closed volume is conserved, i.e., particles can only be redistributed in the volume,

$$
\int_0^\infty R^2 \dot{\Phi}(R) dR = \dot{\Phi}(k = 0) = 0.
$$

The latter yields $\varphi = -\pi/2$ for $\ln \dot{S}_c > 1$ and $\Gamma \ll 1$. When $C^2 - \kappa > 0$, the solution (C19) cannot be matched with solutions (C18) and (C20). Thus, the condition $C^2 - \kappa < 0$ is the necessary condition for the existence of the solution for the
correlation function. The condition $C>0$ provides the existence of the global maximum of the correlation function at $R=0$.

Matching the functions $\hat{F}$ and $\hat{F}'$ at the boundaries of the above-mentioned regions yields coefficients $A_k$ and $\gamma_0$. In particular, the growth rate of the clustering coefficient $\gamma_2$ is determined by Eq. (43).

In Models I and II of a random velocity field the correlation functions of incompressible $F(R)$ and compressible $F_c(R)$ components are proportional to $1-R^2$ up to the scale $\eta$ [see, e.g., Eq. (45)]. We showed also that in the dissipative range $B>0$ (which implies the generation of passive scalar fluctuations) and $B(R)$ sharply decreases in the inertial range. Therefore, it is plausible to suggest that the Kolmogorov dissipation scale is the only length scale that determines the clustering instability scale. On the other hand, the turbulent diffusion time in Model II of a random velocity field is $\tau_\eta = \eta^2/(\tau_{\text{rad}} \eta^2) = \tau_\eta/Sr$. Thus, in Model II of a random velocity field, the time $\tau_\eta$ is the characteristic time of the clustering instability.
